FIGURE 105-14 ■ Examples of the five types of atrioventricular alignments.* **A**, Concordant. The left figure is the usual alignment in situs solitus (right-sided right atrium [RA] aligned with right-sided right ventricle [RV] and left-sided left atrium [LA] aligned with left-sided left ventricle [LV]), but atrioventricular alignment is concordant as well if both atria and ventricles are inverted (*right panel*). **B**, Discordant. In the *left panel*, atrioventricular alignment discordance is due to ventricular inversion in situs solitus (right-sided right atrium aligned with a right-sided [inverted] left ventricle and a left-sided [inverted] right ventricle), which can be associated with isolated ventricular inversion {S,L,S}, an anatomically corrected malposition {S,L,D}, congenitally corrected transposition {S,L,L}, superior-inferior ventricles with double-outlet right ventricle {S,L,D}, and others. Note that the mirror images of these arrangements in situs inversus also produce atrioventricular alignment discordance (e.g., isolated ventricular noninversion {I,D,I}, anatomically corrected malposition {I,D,L}, congenitally corrected transposition {I,D,D}). Isolated atrial inversion (*right panel*), such as normally related great arteries {I,D,S}, also results in atrioventricular alignment discordance. **C**, Straddling atrioventricular valve. The example shows straddling tricuspid valve (*left panel*) and straddling mitral valve (*right panel*) in atrioventricular situs concordance (as in **A**) but could be situs discordance (as in **B**) as well. Although concordance–discordance works for situs, it does not work for alignment. What is the alignment of the right atrium in the left figure or the left atrium in the right figure? It is both concordant and discordant, because the atrium with the straddling valve is aligned with both ventricles through the normal and straddling orifices of the valve. **D**, Double-inlet ventricle. In the *left panel*, there is double-inlet left ventricle with atrioventricular situs discordance {S,L,_} (solitus atria with a right-sided right atrium and left-sided left atrium, but l-loop or inverted left ventricle with the outlet chamber to the left and the left ventricle to the right). Situs concordance is possible as well (e.g., double-inlet left ventricle with normally related great arteries {S,D,S}, also known as Holmes heart, which is not shown). The *right panel* illustrates double-inlet right ventricle with atrioventricular situs concordance {S,D,_} (the right atrium is right-sided and the left atrium left sided, the ventricles are solitus or d-loop with a right-sided right ventricle and a left-sided hypoplastic left ventricle). Concordance–discordance does not work for atrioventricular alignment in this case because both atria are aligned with the same ventricle so that the alignment of one atrium is concordant and the other discordant. **E**, Atrioventricular valve atresia. The *left panel* illustrates mitral atresia in atrioventricular situs concordance {S,D,_} (solitus atria with the right atrium to the right and the left atrium to the left and d-loop or solitus ventricles with the right ventricle to the right and the hypoplastic left ventricle to the left). This could also occur in situs inversus (the mirror image of the example shown) or in atrioventricular situs discordance, such as {S,L,_} with right-sided mitral atresia. The *right panel* shows tricuspid atresia in atrioventricular situs discordance {S,L,_} (solitus atria with a right-sided right atrium and left-sided left atrium and a right-sided inverted [l-loop] left ventricle and left-sided outlet chamber). Here the right atrial alignment is discordant, but the left atrial alignment is neither concordant nor discordant because it does not drain directly into either ventricle. It drains across the atrial septum into the right atrium. This could occur in atrioventricular situs concordance as well, such as tricuspid atresia with transposition {S,D,D}. Note that it is also possible for the remaining atrioventricular valve to straddle the septum. *Although we have stressed in the text that the ventricular loop or situs is based on the chirality or handedness of the chamber and not its position in space, we have used position as a surrogate for ventricular loop or situs in this and the next figure to facilitate creating the illustrations.

arteries. Consequently, the single arterial root is essentially never a pulmonary trunk.

Segmental Connections

Finally, the connections of the segments are described. Alignment and connection are different and both are important. As noted above, the three main segments

are not connected directly to each other. Rather, they are joined by the two connecting segments. Atrioventricular connections are (1) two valves into separate ventricles, (2) common valve into two ventricles, (3) straddling AV valve, (4) two valves into one ventricle, (5) common valve into one ventricle, (6) absent AV connection, and (7) imperforate AV valve. Atrioventricular alignments and connections are closely related. For example,

FIGURE 105-15 ■ Examples of the five types of ventriculoarterial alignment.* **A**, Concordant. The *left panel* shows normally related great arteries in situs solitus {_, D, S} (rightward and posterior aorta aligned with the left ventricle [LV] and connected by mitral-aortic fibrous continuity and the leftward, anterior pulmonary artery aligned with the right ventricle [RV] and connected by a subpulmonary conus). Ventriculoarterial alignment is also concordant in normally related great arteries in situs inversus {_, L, I} (the mirror image of the *left panel*, not shown), anatomically corrected malposition {_, D, L} (*middle panel*, left-sided d-loop left ventricle aligned with a left-sided aorta and connected by a subaortic conus, right-sided d-loop right ventricle aligned with the right-sided pulmonary artery and connected by a [often deficient] subpulmonary conus) or {_, L, D} (the mirror image of {_, D, L}, not shown), isolated infundibuloarterial discordance {S, D, I} (*right panel*, right-sided d-loop right ventricle aligned with a right-sided and anterior pulmonary artery and connected by subpulmonary conus, and a left-sided d-loop left ventricle aligned with a leftward and posterior aorta and connected by aortic-mitral fibrous continuity) or {I, L, S}, its mirror image, and others. **B**, Discordant. The *left panel* shows common transposition of the great arteries {S, D, D} (right-sided d-loop right ventricle aligned with the right-sided aorta and connected by subaortic conus and the left-sided d-loop left ventricle aligned with the leftward pulmonary artery and connected by pulmonary-mitral fibrous continuity). The *right panel* shows congenitally corrected transposition {S, L, L} (right-sided inverted or I-loop left ventricle aligned with the right-sided pulmonary artery and connected by pulmonary-mitral fibrous continuity and the left-sided inverted or I-loop right ventricle aligned with the left-sided aorta and connected by subaortic conus). **C**, Double-outlet ventricle. The *left panel* shows double-outlet right ventricle {S, D, D} (a right-sided d-loop right ventricle is aligned with both great arteries [the right-sided aorta and left-sided pulmonary artery], whereas the left-sided d-loop left ventricle is aligned with neither). The *right panel* shows double-outlet left ventricle {S, D, D} where both great arteries are aligned with the left ventricle and neither with the right ventricle. Concordance–discordance does not make sense in this context because one ventricle is aligned with both great arteries and the other with neither. In the illustration, the great arteries are connected to the right ventricle, in the case of double-outlet right ventricle, by bilateral subarterial conus and to the left ventricle, in the case of double-outlet left ventricle, by fibrous continuity between the mitral valve and both semilunar valves. Keep in mind, however, that more than one type of ventriculoarterial connection can occur with either type of double-outlet ventricle. **D**, Overriding single arterial trunk. The *left panel* shows tetralogy of Fallot with pulmonary atresia and no pulmonary trunk, considered to be a type of normally related great arteries. However, both ventricles are aligned with the overriding single aortic root, so that concordance–discordance does not really apply. The alignment is the same in typical truncus arteriosus with an overriding truncal root (*right panel*). In the great majority of such cases, there is semilunar-mitral fibrous continuity as shown in the illustration. **E**, Right ventricular single arterial trunk. In truncus arteriosus with complete subtruncal conus (*left panel*) the truncal root is completely above and aligned with the right ventricle. The left ventricle is not aligned with a great artery and ejects through the ventricular septal defect. The *right panel* demonstrates a right ventricular aorta with pulmonary atresia. The aorta is aligned with the right ventricle, but the left ventricle is not aligned with a great artery. Concordance–discordance is not useful for describing this arrangement. *Although we have stressed in the text that the ventricular loop or situs is based on the chirality or handedness of the chamber and not its position in space, we have used position as a surrogate for ventricular loop or situs in this and the previous figure to facilitate creating the illustrations. The cylinder indicates subarterial conus or infundibulum.

double-inlet alignment can only be associated with two valves or a common valve into one ventricle. The term *AV valve atresia* has been used both for conditions with absent connection (usual tricuspid atresia) and for conditions in which valve components are present but there is

no orifice (many cases of mitral atresia). This is unlikely to change, nor is such a change being proposed. However, distinguishing between these types of atrioventricular connection is likely to be informative regarding developmental mechanism and possibly outcome.

Ventriculoarterial connection and alignment are less closely related. The aorta might be connected normally to the left ventricle with fibrous continuity between the mitral and aortic valves (normally related great arteries) or abnormally by a muscular conus between the left ventricle and the aorta (anatomically corrected malposition). In both cases, the ventriculoarterial alignment is concordant; the aorta receives blood from the left ventricle and the pulmonary artery from the right ventricle. However, the ways in which the great arteries are connected to the ventricles differ. A given ventriculoarterial alignment can be associated with multiple types of connection. This has implications for associated abnormalities (e.g., the subaortic conus in anatomically corrected malposition can become obstructed) and surely for the developmental mechanisms that produce the defect.

There are four ventriculoarterial connections: subpulmonary conus only, subaortic conus only, bilateral subarterial conus, and bilaterally absent subarterial conus. A subpulmonary conus is typical of normally related great arteries, but it can occur with a rare form of transposition with a posterior aorta, with double-outlet right ventricle with mitral atresia, and with isolated infundibuloarterial discordance.¹⁵ Subaortic conus is typical of common and congenitally corrected transposition, but it occurs in some forms of double-outlet left ventricle.¹⁶ Bilateral conus is most often associated with double-outlet right ventricle, but it can occur with transposition¹³ and anatomically corrected malposition. Bilaterally absent subarterial conus is seen in double-outlet left ventricle,¹⁶ but it can also occur in transposition.¹³ As already noted, the ventriculoarterial connection has implications for outflow obstruction, great artery size, and arterial obstruction.

Disharmony between Situs and Alignment

There is typically concordance or harmony among the atrial situs, the loop or situs of the ventricles, and the situs or position of the great arteries. When the atrial situs is solitus, there are usually d-loop ventricles and the aorta is usually to the right—either solitus normally related great arteries or some type of d-malposition of the great arteries—and conversely in situs inversus.

Situs discordance between segments is a feature of a number of heart defects. For example, in congenitally corrected transposition {S,L,L}, there is atrioventricular situs discordance (solitus atria but inverted ventricles) and alignment discordance (right atrium aligned with right-sided left ventricle and left atrium aligned with a left-sided right ventricle). The situs correctly predicts the atrioventricular alignments; this is the case in the vast majority of hearts.

However, some hearts are characterized by discrepancy or disharmony between segmental situs and segmental alignments.^{4,17,18} In the vast majority of hearts, when there is situs solitus of the atria and d-loop ventricles, or situs inversus and l-loop ventricles, the right atrium is aligned with (drains into) the right ventricle and the left atrium is aligned with the left ventricle. The situs of the segments correctly predicts the alignments. There is said to be concordance or harmony between situs and

alignments. It is mostly in hearts with superoinferior ventricles and crisscross hearts where one sees discordance or disharmony between situs and atrioventricular alignment: a solitus right atrium aligned with a d-loop left ventricle and a solitus left atrium aligned with a d-loop right ventricle (and the converse). Especially in these hearts, one cannot assume that situs correctly predicts atrioventricular alignments. Virtually all the hearts with situs-alignment discordance that have been reported also have right juxtaposition of the atrial appendages.¹⁸ In other types of hearts, it seems a practical assumption that situs correctly predicts atrioventricular alignment.

Situs and ventriculoarterial alignment are less tightly linked. Often one cannot deduce the ventriculoarterial alignment from the situs of the ventricles and great arteries. For example, a heart with the cardiotype {S,D,D} could be transposition (discordant) or double-outlet ventricle (right or left). Or the cardiotype {S,D,L} could be associated with transposition (discordant), anatomically corrected malposition (concordant) or double-outlet ventricle. Sometimes this is because the concept of concordance and discordance does not apply, as in double-outlet ventricle. Other times it simply reflects the variability of arterial position. Consequently, the ventriculoarterial alignment is typically stated in the diagnosis along with the cardiotype (e.g., anatomically corrected malposition {S,D,L}).

Examples of Segmental Analysis

The following examples illustrate the use of segmental analysis.

1. Normal heart in situs solitus
 - a. Segmental situs: atrial situs solitus {S,_,_}; ventricular d-loop or situs solitus {_,D,_}; solitus normally positioned and related great arteries {_,_,S}. The cardiotype, using set notation, is {S,D,S}.
 - b. Segmental alignments: the atrioventricular alignment is concordant; the ventriculoarterial alignment is concordant (see [Figs. 105-14A](#) and [105-15A](#)).
 - c. Segmental connections: the atrioventricular connection is two valves into separate ventricles; the ventriculoarterial connection is subpulmonary conus only with mitral-aortic fibrous continuity.

The normal heart in situs inversus has the cardiotype {I,L,I} (situs inversus [I]; ventricular l-loop or situs inversus [L]; inversus normally related great arteries [I]), but the alignments and connections are the same as noted previously.

In these hearts, the location, alignments, and connections of the heart segments are all appropriate so that any hemodynamic abnormality is due to one or more of the myriad possible other defects such as a venous drainage anomaly, abnormal intracardiac communication, outflow obstruction, and so on.

2. Common transposition of the great arteries
 - a. Segmental situs: atrial situs solitus {S,_,_}; ventricular d-loop or situs solitus {_,D,_};

transposition of the great arteries with the aorta anterior and rightward {_,_,D}. The cardiotype is {S,D,D}.

- b. Segmental alignments: the atrioventricular alignment is concordant; the ventriculoarterial alignment is transposition (discordant; see Figs. 105-14A and 105-15B).
 - c. Segmental connections: the atrioventricular connection is two valves into separate ventricles; the ventriculoarterial connection is usually subaortic conus with pulmonary-mitral fibrous continuity, but, as noted, can be variable.
- Here there is a single segmental alignment discordance between the ventricles and great arteries. The patient is blue because systemic venous blood from the right atrium is recycled back to the aorta through the right ventricle. Creating ventriculoarterial alignment concordance by performing an arterial switch operation corrects the abnormal blood flow pattern and places the left ventricle in the systemic circulation.

3. Double-outlet right ventricle with straddling mitral valve

- a. Segmental situs: atrial situs solitus {S,_,_}; ventricular d-loop or situs solitus {_,D,_}; double-outlet ventricle with aorta rightward {_,_,D}. The cardiotype is {S,D,D}.
- b. Segmental alignments: the atrioventricular alignment is mitral straddling. The right atrium is normally aligned with the right ventricle; the left atrium is aligned partially with both ventricles. The ventriculoarterial alignment is double-outlet ventricle (right; see Figs. 105-14C and 105-15C).
- c. Segmental connections: the atrioventricular connection is two valves into separate ventricles with straddling of the mitral valve; the ventriculoarterial connection could be subaortic conus with fibrous continuity between the pulmonary valve and the straddling part of the mitral valve or bilateral subarterial conus.

The information conveyed by the situs, alignments, and connections is essential, but other important information must be supplied before a treatment plan can be formulated, including relation of the arterial roots to the ventricular septal defect (if one is present); presence, severity, and mechanism of outflow obstruction; and ventricular hypoplasia that might preclude a biventricular repair. Details of the mitral straddling are also important for surgical planning.

4. Anatomically corrected malposition of the great arteries

- a. Segmental situs: atrial situs solitus {S,_,_}; ventricular d-loop or situs solitus {_,D,_}; anatomically corrected malposition with the aorta to the left {_,_,L}. The cardiotype is {S,D,L}.
- b. Segmental alignments: the atrioventricular alignment is concordant. The right atrium is normally aligned with the right ventricle; the left atrium is normally aligned with the left ventricle. The ventriculoarterial alignment is concordant.

The left-sided aorta is aligned with the left-sided left ventricle, and the right-sided pulmonary artery is aligned with the right-sided right ventricle (see Figs. 105-14A and 105-15A).

- c. Segmental connections: the atrioventricular connection is two valves into separate ventricles; the ventriculoarterial connection is bilateral conus, although the subpulmonary conus is often deficient.

Anatomically corrected malposition {S,D,L} is the most frequent type. There is no alignment discordance here; therefore, ventricular septal defect closure might be all that is needed. This defect illustrates the difference between alignment and connection. Although the ventriculoarterial alignments are concordant (right ventricle–pulmonary artery and left ventricle–aorta), the connections are abnormal. There is typically a long subaortic conus or infundibulum connecting the aorta with the left ventricle and a deficient subpulmonary conus connecting the pulmonary artery with the right ventricle. Outflow obstruction can occur on either or both sides because of the abnormal conus or infundibulum.

There are types of anatomically corrected malposition with atrioventricular discordance (e.g., {S,L,D}). There is ventriculoarterial alignment concordance, because the right-sided left ventricle is aligned with the right-sided aorta and the left-sided right ventricle is aligned with the left-sided pulmonary artery, but the ventriculoarterial connections are abnormal as described previously. Here an atrial switch operation might be indicated to correct the segmental (atrioventricular) alignment discordance, but an arterial switch operation would not be so because there is already ventriculoarterial alignment concordance.

5. Isolated infundibuloarterial inversion

- a. Segmental situs: atrial situs solitus {S,_,_}; ventricular d-loop or situs solitus {_,D,_}; inverted normally related great arteries {_,_,I}. The cardiotype is {S,D,I}.
- b. Segmental alignment: the atrioventricular alignment is concordant; the ventriculoarterial alignment is concordant (see Figs. 105-14A and 105-15A). The posterior and leftward aorta is aligned with the left-sided left ventricle, and the anterior rightward pulmonary artery is aligned with the right-sided right ventricle.
- c. Segmental connections: the atrioventricular connection is two valves into separate ventricles; the ventriculoarterial connection is subpulmonary conus with aortic-mitral fibrous continuity.

This is an example of segmental situs discordance ({_,D,I}) with segmental alignment concordance. Although this anomaly can occur with an otherwise essentially normal heart, it is usually associated with subvalvar and valvar pulmonary stenosis. The conotruncus is similar to inverted tetralogy of Fallot.¹⁵ The patient is blue because of pulmonary outflow obstruction with

a right-to-left shunt through the ventricular septal defect rather than to an alignment discordance. The right coronary artery arises from the left-sided aorta and passes to the right AV groove in front of the obstructed pulmonary outflow, which can complicate treating this anomaly as one might treat tetralogy of Fallot.

SUMMARY

The segmental analysis provides a comprehensive understanding of the organization of the heart and the principal diagnoses. This type of analysis indicates whether cyanosis is due to alignment discordance or some other local problem (e.g., pulmonary atresia with atrial right-to-left shunt). If alignment discordance is part of the problem, segmental analysis also indicates the type of operation needed (e.g., atrial switch for isolated atrioventricular alignment discordance, arterial switch for isolated ventriculoarterial alignment discordance, double switch for both atrioventricular and ventriculoarterial [double] alignment discordance). Specific local diagnoses (e.g., additional muscular ventricular septal defect, subaortic stenosis, persistent ductus arteriosus) are then added to the context of the segmental analysis. It is useful to think of the heart segment by segment when establishing the comprehensive diagnosis—from veins, to atria, to atrioventricular valves, to ventricles, to outflow tracts, to great arteries—to avoid missing any component. Organizing the information segmentally in the diagnostic report not only helps to avoid oversight, it also lets the reader know where to find information about any specific part of the heart.

Acknowledgment

I would like to acknowledge and thank Dr. Richard Van Praagh for being a mentor, colleague, and friend over many years and for writing the previous version of this chapter, which was extremely helpful in preparing the current version. I also acknowledge Dr. Paul Weinberg for originating or contributing to many of the concepts expressed in this chapter. I am grateful to Dr. Tal Geva for reviewing the chapter and making some excellent contributions.

SUMMARY

Before the advent of cardiopulmonary bypass in the mid-1950s, little attention was given to the diagnosis of congenital heart disease (CHD) because no effective treatment was available. Physical examination, auscultation, electrocardiography, and radiography were the main diagnostic tools. Progress in open-heart techniques for repair of CHD required accurate and comprehensive delineation of cardiovascular anatomy and function. During the 1960s and 1970s, cardiac catheterization and angiography were the principal tools used to diagnose CHD. Echocardiography entered the arena in the late 1970s. The diagnostic capability of M-mode echocardiography proved insufficient in patients with CHD, but the rapid evolution of two-dimensional

echocardiography during the following decade transformed the field. The technologic advances in transducer design, image processing, and image display—together with development and refinement of new imaging planes and examination techniques—allowed high-quality tomographic visualization of most cardiac defects.¹ The application of Doppler ultrasound to investigate blood flow allowed comprehensive hemodynamic assessment. By the mid-1980s, much of the necessary anatomic and hemodynamic information required for patient management could be obtained noninvasively, obviating the need for a diagnostic catheterization in many patients. During the late 1990s and into the 2000s, the field of pediatric cardiac imaging experienced accelerated progress in areas

such as three-dimensional echocardiography, sophisticated techniques for assessment of myocardial function, and the application of magnetic resonance imaging (MRI) to CHD. At the same time, the proportion of cardiac catheterization procedures performed solely for diagnostic purposes has drastically declined. More recently, the role of multimodality cardiac imaging for preintervention planning and for guidance of cardiovascular procedures has expanded dramatically.²

This chapter discusses the clinical application of the two main noninvasive diagnostic imaging modalities used for anatomic and physiologic evaluation of preoperative and postoperative CHD: echocardiography and cardiovascular MRI.

ECHOCARDIOGRAPHY AND DOPPLER ULTRASOUND

Echocardiography is an ideal diagnostic tool in pediatric cardiology because of its noninvasive nature, relatively low cost, superb spatial and temporal resolutions, and ability to image cardiovascular anatomy and to evaluate physiology in real time. In addition, modern cardiac ultrasound equipment is portable and adaptable to different environments, such as the operating room, intensive care unit, at the bedside, and in an outpatient office setting. In today's pediatric cardiology practice, echocardiography is the primary diagnostic modality used to evaluate anatomy and physiology preoperatively, intraoperatively, postoperatively, during follow-up of CHD, and prenatally.¹⁻³

Description of Technique

To obtain an echocardiographic image, a burst of ultrasound energy is generated by a piezoelectric crystal and travels through the soft tissue at an average speed of approximately 1540 m/sec. When the propagating ultrasound wave encounters an interface between tissues with different acoustic properties, some of the energy is reflected back toward the transducer and some of the energy is refracted and continues to travel in the medium until it encounters the next interface. The returning ultrasound energy is captured by the piezoelectric crystal and converted into an electrical energy that goes through a series of electronic processes, including amplification, filtering, postprocessing, and display.

M-Mode Echocardiography

A narrow beam of ultrasound energy is emitted toward the heart, and structures along the beam path reflect echoes back toward the transducer. A dot is displayed on the screen in a position corresponding to its distance from the transducer. This process is repeated rapidly to create an image. The distance from the transducer is displayed on the y-axis and time is displayed on the x-axis (Fig. 106-1). This provides an anatomic one-dimensional image of the heart that is characterized by excellent temporal and axial resolutions. In today's clinical pediatric echocardiography, two-dimensional imaging

FIGURE 106-1 ■ M-mode tracing of the left ventricle and the aortic root. Ao, Aortic root; IVS, interventricular septum; LV, left ventricle; MV, mitral valve; RV, right ventricle; RVFW, right ventricular free wall.

FIGURE 106-2 ■ Two-dimensional image from the parasternal long-axis view showing the left atrium (LA), left ventricle (LV), aortic root (Ao), descending aorta (DAo), and right ventricle (RV).

has replaced M-mode for anatomic imaging of the heart and for assessment of ventricular size and function.⁴ In selected circumstances, when superior temporal resolution is required, two-dimensional directed M-mode is used to assess motion of specific structures such as native and prosthetic valve leaflets.

Two-Dimensional Echocardiography

By rapidly sweeping an ultrasound beam through an arc, multiple “M-mode lines” are placed next to each other to construct a cross-sectional two-dimensional image of the heart (Fig. 106-2). This can be accomplished by electronically sweeping the sound beam through multiple

piezoelectric crystals (transducer elements), as in phased array transducers. Recent advances in transducer technology and image processing permit very high frame rates (>200 Hz), a feature that greatly enhances temporal resolution.⁵

Three-Dimensional Echocardiography

Accurate spatial perception of an object depends on recognition of its three dimensions: length, width, and depth. Although an experienced examiner can mentally construct a three-dimensional image of the heart from serial two-dimensional tomographic images obtained by sweeping the transducer across the heart, three-dimensional echocardiography offers enhanced perspective of cardiovascular structures and their interrelations. Previous approaches to obtaining three-dimensional echocardiographic images of the heart were based on computer reconstruction of contiguous two-dimensional cross-sectional images. These efforts were hampered by difficulties in accurately registering the ultrasound image data in time and space and by long processing times. Currently, three-dimensional images are generated by real-time three-dimensional echocardiography. This technology, which is based on a new generation of matrix array transducers with several thousands of simultaneously transmitting and receiving piezoelectric elements and sophisticated parallel data processing, provides real-time three-dimensional images with sufficient temporal resolution to display in cine-loop format (Fig. 106-3).⁶⁻⁸ More recently, miniaturization of matrix array transducer technology has allowed development of a real-time three-dimensional transesophageal echocardiographic probe.⁹ Further refinements of this technology will result in continued improvement of spatial and temporal resolutions as well as better, more intuitive, user interface. Such

FIGURE 106-3 ■ Three-dimensional echocardiographic imaging of a prosthetic mitral valve (MV) seen from the atria. TV, Tricuspid valve.

advances will likely contribute to the ongoing acceptance of this technology in routine practice.

Doppler Echocardiography

The use of Doppler ultrasound to assess normal and abnormal hemodynamics has become an integral part of the echocardiographic examination.^{4,10} The advent of two-dimensional directed Doppler interrogation has greatly enhanced the clinical application of this technique by allowing evaluation of flow characteristics in specific regions within the heart and great vessels. In today's echocardiography, spectral and color-coded Doppler flow mapping are used extensively to measure velocity and direction of blood flow (Fig. 106-4). Calculations based on Doppler-derived measurements allow quantitative estimation of flow volume (such as cardiac output), pressure gradient across a stenotic region, cross-sectional flow area, and prediction of intracardiac pressures. Doppler echocardiography also provides qualitative and semiquantitative assessment of valve regurgitation, intra- and extracardiac shunts, as well as myocardial motion (tissue Doppler imaging). Detailed discussion of Doppler physics is beyond the scope of this text and can be found elsewhere.¹¹

Speckle-Tracking Echocardiography

Speckle-tracking echocardiography (STE) is an echocardiographic technique that allows depiction and measurements of myocardial motion and function. The technique is based on frame-to-frame analysis of changes in the unique ultrasonic backscatter features (speckles) of sequential two-dimensional images while filtering out noise. STE displays local displacement of the myocardium that can be then analyzed for indices of myocardial deformation such as strain and strain rate, in any direction within the two-dimensional image (Fig. 106-5).¹² The technique, which was introduced in 2004,¹³ has been validated in an animal model against sonomicrometry and in vivo against cardiac MRI tagging.^{14,15} Advantages of STE over Doppler-based techniques for assessment of tissue motion include independence of angle of interrogation and insensitivity to tethering of the myocardium. More recently, three-dimensional STE has been developed and validated.¹⁶ A review of the use of STE in CHD can be found elsewhere.¹⁷

Contrast Echocardiography

As early as the late 1960s, Gramiak and colleagues¹⁸ noted that intravascular injection of almost any solution resulted in a contrast effect detectable by echocardiography. Initially, this technique was used to identify structures seen by M-mode echocardiography. Contrast echocardiography has been used to detect systemic¹⁹ and pulmonary venous anomalies,²⁰ and for the detection of intracardiac and great artery level shunts.²¹ In today's pediatric echocardiography, contrast studies are infrequently performed and are usually limited to detection of intracardiac shunts in patients with limited echocardiographic windows, patch or baffle leak after cardiac surgery, and in pulmonary arteriovenous malformations.³

FIGURE 106-4 ■ Doppler echocardiography. Visualization of a high-velocity jet by color Doppler aids in aligning the continuous wave Doppler cursor in a patient with severe aortic valve stenosis (maximal instantaneous and mean gradients $\approx$ 126 and 73 mm Hg, respectively).

FIGURE 106-5 ■ Speckle-tracking echocardiography. Left panel: Apical four-chamber view with velocity vector mapping of the left ventricle. Right upper panel: Longitudinal strain versus time curves in six segments of the left ventricular wall. Right lower panel: Longitudinal strain rate versus time curves in the same segments.

Objectives of the Echocardiographic Examination

The objectives of the echocardiographic examination must be tailored to the individual patient. The initial

evaluation should include a comprehensive survey of all anatomic elements of the central cardiovascular system.¹⁰ Subsequent examinations are often targeted to answer specific clinical questions. It is important, however, to repeat complete echocardiograms during follow-up, even

in patients who underwent a comprehensive initial examination, because of the dynamic nature of CHD. Examples include the late onset of discrete subaortic stenosis in patients with ventricular septal defect and/or coarctation of the aorta,²² double-chambered right ventricle,²³ and supramitral stenosing ring.²⁴

Examination Technique

Proper planning of the echocardiographic examination is important to ensure that all diagnostic information is obtained most efficiently. This is particularly relevant in sedated patients in whom the time available for data acquisition is limited. Ideally, a complete segmental examination of cardiovascular anatomy and function should be performed in every new patient. This includes determination of visceral situs, heart position, atrial situs, systemic and pulmonary venous connections, ventricular situs, atrioventricular and ventriculoarterial alignments and connections, and coronary and great arterial anatomy. Assessment of ventricular function, intracardiac and vessel dimensions, and flow analysis across all valves, septa, chambers, and vessels are integral parts of the examination. Echocardiographic techniques include two-dimensional and three-dimensional imaging, blood flow imaging by color Doppler, measurements of flow velocities by pulsed and continuous wave Doppler, and assessment of myocardial function by tissue Doppler or STE. In young children with suspected heart disease, the examination begins from the subxiphoid approach by determining the abdominal situs and then proceeding by scanning the heart and great vessels, using a step-by-step segmental analysis (Fig. 106-6*A* and *B*).^{10,25,26} This approach is advantageous because it provides a wide-angle view of heart position and cardiovascular anatomy and function at an early stage in the examination. Subsequent two-dimensional and Doppler analyses from the apical, parasternal, and suprasternal notch views supplement and confirm findings from the subxiphoid window (see Fig. 106-6*C-G*). The examination strategy should be tailored to the individual patient and modified according to the clinical situation as necessary. Although the standard views just described should be obtained in almost every patient and represent the minimum acceptable examination, flexibility and improvisation are important to optimally use the full potential of echocardiography.

Anatomic Analysis

When performing and reviewing an echocardiographic examination in a patient suspected of having CHD, a stepwise segmental approach to analysis of cardiac anatomy is taken. Each component of the heart is analyzed separately according to its unique morphologic features.^{25,26} The heart is composed of five segments—three main segments and two connecting segments. The three main segments are the atria, the ventricles, and the great arteries. The atrioventricular canal, which includes the mitral and tricuspid valves and the atrioventricular septum, connects the atria with the ventricles. The infundibulum (or conus) connects the ventricles with the great arteries. When analyzing cardiac anatomy, each cardiac

chamber must be identified individually according to its unique anatomic-morphologic features and not according to its spatial position (right-sided or left-sided), valve of entry, or artery of exit. Throughout a systematic echocardiographic study, the examiner must go over a mental checklist of segments, their anatomic organization and position (situs), their connections and alignments with adjacent segments, and associated malformations. Using the aforementioned principles, any potential CHD can be accurately described in specific and precise terms. A detailed review of echocardiographic analysis of each cardiac segment can be found elsewhere.^{10,25}

SPECIAL ECHOCARDIOGRAPHIC PROCEDURES

Transesophageal Echocardiography

Transesophageal echocardiography (TEE) was first introduced in 1976 and appeared in pediatric use in 1989. The miniaturization of probes and development of multiplanar imaging have greatly increased its role as an adjunct to transthoracic imaging, during surgical repair of CHD (intraoperative TEE), and to guide interventional catheterization procedures. Advances in transducer technology and image processing now allow real-time three-dimensional TEE.⁹

Indications and Objectives

A TEE examination is usually performed to answer specific clinical questions. It is advisable, however, to perform a comprehensive examination of the heart and blood vessels for additional unsuspected anatomic and/or hemodynamic anomalies (Fig. 106-7).²⁷ Miniaturization of TEE probes designed for use in young infants weighing 3 to 3.5 kg or less has greatly enhanced the scope of TEE in the pediatric age group.²⁸⁻³¹ Successful TEE examinations have been reported in patients weighing as little as 2.3 kg.^{32,33} The role of TEE in pediatric cardiology is continuously evolving. Although the transthoracic window is adequate in most situations, TEE provides distinct advantages during cardiovascular surgery,^{28,30,33} during video-assisted thoracoscopic procedures,³⁴ for guidance of interventional catheter procedures,^{35,36} in the intensive care unit,^{28,37} for detection of intracardiac thrombi and vegetations,³⁸ in the assessment of prosthetic valves,³⁹ in selected patients on mechanical assist device and extracorporeal membrane oxygenator,⁴⁰ and in selected patients with poor transthoracic windows, such as adults with CHD.⁴¹ The usefulness of selective versus routine use of intraoperative TEE in patients with CHD deserves further study.^{27,42}

Safety and Complications

Although in expert hands TEE is quite safe, complications have been reported, including oropharyngeal trauma and compression of airways and vascular structures.^{43,44} TEE is contraindicated in patients with an unrepaired tracheoesophageal fistula, esophageal

FIGURE 106-6 ■ Standard two-dimensional transthoracic imaging sweeps. **A**, Subxiphoid long-axis sweep. Slow gradual sweep starting at the level of the upper abdomen will show the connection of the inferior vena cava to the right atrium (RA). The left atrium (LA) is seen next. The connection of the pulmonary veins and the atrial septum can be demonstrated from this view. The left ventricle (LV) is seen along its long axis. Further superior angulation of the transducer depicts the left ventricular outflow tract, aortic valve, and ascending aorta (Ao). The superior vena cava (SVC) is seen to the right of the Ao and the main pulmonary artery (MPA) is seen to the left of the aorta. Further superior tilt of the transducer shows the inflow and outflow of the right ventricle (RV) and the pulmonary valve. The sweep ends with anterior free wall of the right ventricle. **B**, Subxiphoid short-axis sweep. From the subxiphoid long-axis view, the transducer is rotated clockwise approximately 90 degrees. The sweep begins at the rightward-most aspect of the heart and progresses from right to left through the cardiac apex. The superior vena cava (SVC) and inferior vena cava are seen entering the right atrium (RA). The right pulmonary artery (RPA) is seen in cross-section behind the SVC and above the left atrium (LA). The atrial septum is well seen in this plane. Sweeping the transducer leftward will show the base of the left ventricle (LV) and right ventricle (RV) and the atrioventricular valves. The aortic valve is seen in cross-section at this level. Further leftward tilt of the transducer depicts a cross-sectional view of the LV and mitral valve (MV) as well as the right ventricular outflow tract and pulmonary valve (PV). The sweep ends with imaging of the mid-muscular septum, the papillary muscles, and the apical portions of both ventricles. **C**, Apical four-chamber sweep. The transducer is positioned over the apex and angled to obtain a cross-sectional view of the atria and ventricles as shown in level 2. The transducer is then angled posteriorly to image the posterior aspect of the heart (level 3). In this plane, the coronary sinus (CS) can be viewed along the posterior left atrioventricular groove. Antero-superior tilt of the transducer will show the left ventricular outflow tract and proximal ascending aorta (Ao). **D**, Parasternal long-axis sweep. The transducer is placed over the left precordium to the left of the sternum with the index mark toward the patient's right shoulder. A rightward and inferior tilt of the transducer toward the right hip shows the right atrium (RA), tricuspid valve, and right ventricular inflow (RV) (level 1). The coronary sinus can be followed into the right atrium in this view. A leftward and superior tilt of the transducer toward the left shoulder depicts the right ventricular outflow tract (RV), pulmonary valve, and main pulmonary artery (PA) (level 3).

FIGURE 106-6, cont'd ■ **E**, Parasternal short-axis sweep. From the parasternal long-axis view, the transducer is rotated clockwise approximately 90 degrees. The sweep progresses from a plane that shows the right and left atria (RA and LA), atrial septum, tricuspid valve (TV), right ventricle (RV), pulmonary valve (PV), and main pulmonary artery (level 1) toward the apex. Cross-sectional views of the right ventricle (RV), left ventricle (LV), ventricular septum, mitral valve (MV), and papillary muscles (PMs) are obtained. **F**, Aortic arch view from the suprasternal notch window. The innominate vein (Innom. Vein) is seen anterior to the innominate artery. The right pulmonary artery (RPA) is seen in cross-section behind the ascending aorta. **G**, Suprasternal notch view in the transverse plane. The left innominate vein (Innom. V) is seen draining into the superior vena cava (SVC). The distal ascending aorta (Ao) is seen superior to the right pulmonary artery (RPA), which is seen along its length above the left atrium (LA). Note the pulmonary veins entering the left atrium. **H**, High right parasternal view in the sagittal plane view showing the superior vena cava (SVC) entering the right atrium (RA). This view allows demonstration of the sinus venosus septum. IVC, Inferior vena cava; RUPV, right upper pulmonary vein.

obstruction or stricture, perforated viscus, or active gastrointestinal bleeding; in an unwilling or uncooperative patient who is inadequately sedated; or with an uncontrolled airway in a patient with respiratory or cardiac decompensation. Relative contraindications include cervical spine injury, immobility, or deformity; history of esophageal surgery; known esophageal varices or diverticulum; oropharyngeal deformities; and severe coagulopathy.^{27,45,46}

Fetal Echocardiography

Examination of the human fetal cardiovascular system dates back to the late 1960s when continuous wave Doppler was used to record fetal heart rate. Although Kleinman and coworkers⁴⁷ in the late 1970s had some success in detecting CHD in the fetus by M-mode echocardiography, it was not until high-resolution two-dimensional imaging became available in the mid-1980s

that accurate delineation of cardiovascular anatomy became clinically routine. Today, prenatal detection of CHD can be reliably diagnosed by 17 to 20 weeks of gestation by transabdominal imaging. Using the transvaginal window, the heart and great vessels can be imaged as early as late first trimester.⁴⁸

Indications and Objectives

Although several studies have demonstrated a low detection rate of CHD by routine level I obstetric ultrasound,⁴⁹ cost-benefit considerations preclude universal fetal echocardiographic screening by expert pediatric echocardiographers. Alternatively, an approach based on targeting pregnancies that are at high risk for CHD is taken. Such an approach increases the yield of fetal echocardiography to approximately 30% when extracardiac anomalies are detected, to approximately 60% when level I scan detects possible CHD, and to almost 100% when a second

FIGURE 106-7 ■ Transesophageal imaging. **A**, Transverse plane: cross-sectional view at level 1a depicts the proximal ascending aorta (Ao), main pulmonary artery (MPA), and left and right pulmonary arteries (LPA and RPA, respectively). A rightward tilt of the transducer shows the RPA as it passes behind the superior vena cava (SVC) and ascending aorta (Asc Ao). To obtain a four-chamber view (level 3), the transducer is advanced in the esophagus with slight retroflexion of the scope. **B**, Level 2 is parallel to the transthoracic parasternal short-axis view. In level 2a, the atrial septum is imaged by a slight rightward tilt of the transducer. In level 2b, the aortic valve (AoV) is seen in cross-section in the center of the image, and the left atrium (LA), right atrium (RA), tricuspid valve, right ventricular outflow (RV outflow), pulmonary valve (PV), and the proximal main pulmonary artery are seen. By advancing the transducer into the lower esophagus and antelexing the scope, a cross-sectional view of the left ventricle (LV), mitral valve, and papillary muscles (PMs) is obtained (level 4). Note that image orientation is the same as in transthoracic echocardiography. **C**, Vertical (longitudinal) plane: the sweep begins at a plane that crosses the superior vena cava (SVC), left atrium (LA), right atrium (RA), and atrial septum (level 1). Next, a leftward tilt of the transducer shows an image parallel to the transthoracic parasternal long-axis view of the left atrium (LA), mitral valve, left ventricle (LV), left ventricular outflow tract, and proximal aorta (Ao) (level 2). Further leftward tilt of the transducer (level 3) shows the right ventricular outflow tract (RV outlet), pulmonary valve, and main pulmonary artery (MPA). The sweep continues leftward to show the leftward aspects of the left atrium, mitral valve, and left ventricle (level 4). Further leftward tilt depicts the left atrial appendage and the left pulmonary veins (not shown). Note that image orientation is the same as in transthoracic echocardiography. *MV*, Mitral valve.

opinion is requested.^{50,51} The indications for fetal echocardiography are summarized in [Box 106-1](#).

Description of Technique

Echocardiographic examination of the cardiovascular system in the fetus is based on the same principles of the segmental approach to diagnosis of CHD that is applied after birth. The main difference between examination of the fetus and the newborn is that the operator has no control over fetal position and, consequently, over the views obtained. Once fetal position is ascertained and the

spatial coordinates are determined, the examination then continues according to the principles outlined in the previous sections. Given optimal acoustic windows and favorable fetal position, even the most complex cardiovascular anomalies can be detected ([Fig. 106-8](#)).⁵² Defects that remain difficult to diagnose in utero include secundum atrial septal defect, patent ductus arteriosus, small or moderate ventricular septal defect, coarctation of the aorta, and some valve and great vessel abnormalities.⁵³ Distinguishing between normal patency of the foramen ovale and an atrial septal defect is usually not possible in the fetus. Similarly, it is not possible to predict whether

BOX 106-1 Indications for Fetal Echocardiography

FETAL RISK FACTORS

- Extracardiac structural anomalies
- Chromosomal abnormalities
- Fetal dysrhythmias
- Intrauterine growth retardation
- Nonimmune hydrops fetalis
- Multiple gestation and suspicion of twin-twin transfusion syndrome
- Suspected cardiac anomaly on level I scan
- Abnormal visceral situs

MATERNAL RISK FACTORS

- Congenital heart disease
- Exposure to teratogen (sample list only)
 - Lithium carbonate
 - Amphetamines
 - Alcohol
 - Anticonvulsants
 - Phenytoin
 - Trimethadione
 - Isotretinoin
- Exposure to prostaglandin synthetase inhibitors (e.g., ibuprofen, salicylic acid, indomethacin)
- Maternal autoimmune disease
- Maternal diabetes
- Phenylketonuria
- Maternal infection
 - Rubella
 - Toxoplasmosis
 - Coxsackie virus
 - Cytomegalovirus
 - Mumps virus
- In vitro fertilization

FAMILIAL RISK FACTORS

- Congenital heart disease
- Syndromes
 - Down
 - Marfan
 - Noonan
 - Tuberous sclerosis
 - Velocardiofacial
- Familial inherited disorders (e.g., Ellis van Creveld, Marfan, Noonan, etc.)

Modified from Kleinman C: *Fetal echocardiography: diagnosing congenital heart disease in the human fetus. ACC Educational Highlights Summer:10–14, 1996; and Rychik J, Ayres N, Cuneo B, et al: American Society of Echocardiography guidelines and standards for performance of the fetal echocardiogram. J Am Soc Echocardiogr 17:803–810, 2004.*

the normally patent ductus arteriosus will close after birth. In utero diagnosis of aortic coarctation may be difficult because the typical isthmic narrowing may not become apparent until after ductal closure.⁵³ However, the diagnosis may be suspected based on abnormal morphology of the transverse aortic arch (elongation and hypoplasia), size discrepancy between the diameters of the aortic isthmus and patent ductus arteriosus, continuous flow profile in the aortic isthmus, and size discrepancy between the ventricles (right ventricle is larger than left ventricle).^{54,55}

FIGURE 106-8 ■ Fetal echocardiogram in a 24-week-old fetus with a partial common atrioventricular (AV) canal as seen from a four-chamber view. The large deficiency of the atrial septum and apical displacement of the AV valve are clearly seen. A, Anterior; L, left; LV, left ventricle; RV, right ventricle; S, spine.

Clinical Implications

Early prenatal diagnosis of major CHD allows parents to consider the option of terminating the pregnancy. It is also common to recommend amniocentesis to detect associated genetic abnormalities. When pregnancy continues, prenatal diagnosis of CHD allows proper planning for postnatal cardiac care. When intervention is anticipated immediately or shortly after birth (e.g., ductal-dependent anomalies or balloon atrial septostomy in transposition of the great arteries), delivery in a pediatric cardiac center is arranged. The currently available literature provides conflicting views on whether prenatal diagnosis of CHD leads to a significant reduction in mortality.^{56,57} However, there is evidence it can reduce morbidity in certain lesions.⁵⁶ Other advantages, such as psychologic benefits to the parents are also valuable.⁵⁸

Fetal Arrhythmia

One of the major reasons for referral to fetal echocardiography is arrhythmia. Most commonly, irregular fetal heart rate is caused by either conducted or blocked premature atrial contractions. These are usually benign and require follow-up only if they are frequent or associated with supraventricular tachycardia. Among the serious arrhythmias encountered in the fetus, supraventricular tachycardia and atrial flutter are the most common.⁵⁰ Premature ventricular contractions and ventricular tachycardia are rare in the fetus but both have been reported.⁵⁰ Transplacental pharmacologic therapy is indicated in fetuses with incessant tachyarrhythmia, especially if signs of heart failure (e.g., enlargement of cardiac chambers, pericardial effusion and hydrops fetalis) are present. Complete heart block is the most common cause of prolonged bradycardia in the fetus.⁵⁹ The distinction between complete heart block and sinus bradycardia is important because the latter might indicate fetal distress. In fetuses with a structurally

normal heart, maternal lupus erythematosus should be suspected. The most common structural CHD associated with complete heart block are L-loop physiologically “corrected” transposition of the great arteries and heterotaxy syndrome with polysplenia.

Fetal arrhythmias have been traditionally diagnosed by Doppler and M-mode echocardiography.⁵⁰ Both methods rely on simultaneous recording of signals from the atria and ventricles. Fetal position, however, may not always allow optimal alignment of the M-mode cursor or the Doppler beam. Newer methods, tissue Doppler imaging and STE, provide a promising alternative to standard M-mode and Doppler echocardiography.⁶⁰

QUANTITATIVE ANALYSIS

Modern echocardiography allows accurate measurements of cardiovascular structures.⁴ These measurements are helpful in deciding whether the size of a certain structure is within normal limits and in quantifying the degree of deviation from the expected norm.

Adjustment of Measurements to Body Size

Measurements of linear dimensions (such as vessel diameter), cross-sectional areas (such as valve area), or volumetric dimensions (such as ventricular volume or mass) provide important quantitative information that can be used to assess the severity of disease process and to predict its course and prognosis. Because the pediatric age group encompasses a wide range of body sizes and because the heart and great vessels grow considerably from birth to adulthood, measured dimensions must be adjusted to allow meaningful comparisons between patients of different age and body size.⁶¹ For example, the mean value of the aortic valve annulus diameter is 0.74 cm in a 3.6-kg newborn (body surface area 0.24 m²) and 1.95 cm in a 60-kg adolescent (body surface area 1.66 m²). Indexing the aortic annulus diameter to body weight yields vastly different values (0.21 cm/kg in the newborn versus 0.032 cm/kg in the adolescent). Indexing the aortic valve diameter to the body surface area yields similarly unsatisfactory results (3.1 cm/m² in the newborn versus 1.17 cm/m² in the adolescent). Tanner⁶² in 1949 and, more recently, Gutgesell and Rembold⁶³ and Sluysmans and Colan⁶¹ noted that the growth of cardiac structures is not necessarily a linear function of the body surface area, the weight, the height, or the age. These findings are to be expected because the heart and great vessels grow much faster during the first 2 to 4 years of life compared with later childhood and adolescence. It was found that linear dimensions (such as diameters of valves and great vessels) should be indexed to the square root of the body surface area.⁶¹⁻⁶³ Returning to the preceding example of the aortic valve diameter, indexing the valve diameter to the square root of the body surface area yields 0.74/0.49 = 1.51 cm/m^{0.5} in the 3.6-kg newborn and 1.95/1.29 = 1.51 cm/m^{0.5} in the 60-kg adolescent (Fig. 106-9). Cross-sectional measurements (such as valve area) should be indexed to the body surface area.⁶³ Left ventricular volume should be indexed to the body surface

area raised to the power 1.28, and left ventricular mass should be indexed to the body surface area raised to the power 1.23.⁶¹

An alternative approach to comparing measurements between individuals is the use of z-scores.¹ The z-score is a statistical expression of the position of a data point relative to the regression line of a data set. The z-score is expressed as the number of standard deviations from the expected mean of a normal population. It is calculated as follows:

$$z\text{-score} = \frac{\text{measured value} - \text{mean value of normal population}}{\text{standard deviation of normal population}}$$

Returning to the preceding example of aortic valve diameter, the z-value of a 0.74-cm aortic valve diameter in a newborn with a body surface area of 0.24 m² is 0. That means that 0.74 cm is the mean value of aortic valve diameter in infants with that body size. In the adolescent with a body surface area of 1.66 m², the z-value of an aortic valve diameter of 1.95 cm is also 0. In other words, the same z-scores in the newborn and the adolescent indicate that both values are in the same position relative to the regression line of normal values and are comparable. An aortic valve diameter of 0.53 cm in the newborn would have a z-score of -2.0, which indicates that this value is 2 standard deviations below the expected mean. An aortic valve diameter of 0.96 cm in the same newborn would have a z-score of +2.0, which indicates that this value is 2 standard deviations above the mean. Thus, expression of measurements as z-values allows comparison between patients, regardless of differences in body size.

Estimation of left ventricular volume is an important factor in determining the adequacy of chamber size in patients with left ventricular hypoplasia and in the evaluation of patients with volume overload. Numerous algorithms based on several geometric models have been developed for calculation of left ventricular volume. These have been reviewed in detail elsewhere.^{1,3} The biplane Simpson rule is a popular method for estimation of left ventricular volume because of its simplicity. This method requires imaging of the left ventricle from two orthogonal views that share a common long axis: for example, the apical four- and two-chamber views (Fig. 106-10A). Left ventricular volume is calculated according to the following equation:

$$V = \frac{\pi}{4} \times \sum_{i=1}^N a_i \times b_i \times \frac{L}{N},$$

where a_i is the slice radius in the apical two-chamber view, b_i is the slice radius in the apical four-chamber view, L is the left ventricular length, N is the number of slices, and V is the volume.

Another method for estimation of left ventricular volume is the biplane area-length method, where $V = 5/6 \times \text{area} \times \text{length}$ (see Fig. 106-10B). Experience with assessment of left and right ventricular volumes by three-dimensional echocardiography suggests that this technique is more accurate and reproducible than

FIGURE 106-9 ■ Rationale for indexing linear measurements to the square root of body surface area (BSA). **A**, Plot of aortic valve annulus diameter against BSA showing a nonlinear curve. **B**, Plot of aortic valve annulus diameter indexed to BSA against BSA shows that the indexed diameter decreases exponentially as BSA increases. **C**, Aortic valve annulus diameter plotted against the square root of BSA showing a linear relationship. **D**, Plot of aortic valve diameter indexed to the square root of BSA against BSA showing that the indexed aortic valve diameter is the same in children and adults with widely varying body size.

two-dimensional techniques.^{8,64-68} Therefore, it is reasonable to expect that within several years three-dimensional echocardiography will replace two-dimensional methods for measurements of left and right ventricular volumes. Left ventricular myocardial volume can be measured from the two-dimensional echocardiogram by subtracting the endocardial volume from the epicardial volume. Left ventricular mass is calculated by multiplying the resultant myocardial volume by the density of muscle (1.055 g/mL). Because it is not influenced by acoustic windows and is independent of chamber geometry, MRI provides an excellent alternative to echocardiography in measuring chamber volume and mass and is considered the reference standard to which other techniques are compared (see Magnetic Resonance Imaging section, later).

Ventricular Function

Left ventricular function can be assessed at several levels. The heart may be viewed as a pump designed to maintain adequate flow to vital organs.⁶⁹ This approach focuses on the external work performed by the heart, but it ignores the internal work and the functional state of the myocardium. Measuring cardiac output and systemic and pulmonary venous blood pressures can assess the pump function of the heart. It is known, however, that cardiac output and blood pressure can remain within the normal limits despite significant myocardial dysfunction.⁶⁹

Ejection-phase indices of ventricular function, including shortening fraction, fractional area change, ejection fraction, velocity of circumferential fiber shortening (VCF), peak dP/dt, and systolic time intervals, measure global pump function.^{1,4,69} Common to these indices is their dependence on loading conditions. These indices are unable to distinguish between the effect(s) of altered loading conditions and abnormalities in myocardial contractility. Hence, abnormalities in preload and afterload can result in depressed shortening or ejection fractions leading to the erroneous interpretation that myocardial contractility is depressed. Conversely, left ventricular myocardial contractility may be depressed even in the presence of normal shortening or ejection fractions. The advantage of most of these indices is their relative simplicity and ease of acquisition. Load-independent assessment of left ventricular systolic function requires a more sophisticated analysis. The interested reader is referred to the relevant chapters in this book and to other reviews of this topic.⁶⁹

The previously described methods of ventricular function assessment rely in part on measurements of ventricular dimensions. An alternative approach is to evaluate myocardial motion and deformation.⁷⁰ Several methods have been developed to measure myocardial velocities, strain, strain rate, displacement, and torsion (twist). One method uses Doppler to measure myocardial velocities (Doppler tissue imaging [DTI]) and to calculate strain, strain rate, and other variables of tissue deformation

FIGURE 106-10 ■ Methods for assessment of left ventricular volume by two-dimensional echocardiography. **A**, Biplane Simpson rule for calculating left ventricular volume (see text for details). **B**, Area-length method for calculating left ventricular volume. a_i , Slice radius in the apical two-chamber view; b_i , slice radius in the apical four-chamber view; CSA, cross-sectional area; L, left ventricular length; N, number of slices; V, volume.

(Fig. 106-11A).⁷¹⁻⁷³ The other method, STE, analyzes the frame-to-frame changes in ultrasonic signal characteristics and uses that information to track the myocardium throughout the cardiac cycle (see Fig. 106-11B).^{12,74} These methods are independent of ventricular geometry and provide information on systolic and diastolic function.⁷⁵⁻⁷⁷ The reproducibility and the prognostic role of these techniques in patients with CHD are the subject of ongoing investigations.¹⁷

Doppler Evaluation of Pressure Gradients

Estimation of the pressure difference between adjacent compartments has been widely applied in clinical pediatric echocardiography (see Fig. 106-4).^{1,4,10} Among the most common uses is estimation of pressure drop across stenotic areas and prediction of pressure in cardiac

chambers. For example, the systolic pressure in the right ventricle can be predicted from the peak pressure difference between it and the right atrium derived from the peak velocity of the tricuspid regurgitation jet. Right ventricular systolic pressure can also be assessed from knowledge of left ventricular pressure (by measurement of systemic blood pressure by sphygmomanometry) and the pressure drop across a ventricular septal defect. In principle, the pressure gradient across any two compartments connected by flow can be estimated by Doppler, provided that the limitations of the technique are taken into consideration and the sources of error in the application and interpretation of the technique are eliminated.

Calculation of Pressure Gradients

The Bernoulli equation relates pressure difference (ΔP) between two points separated by a distance (s) to the

The velocity-time curve shown on the right panel demonstrates myocardial velocities relative to the apex. **B**, Speckle-tracking evaluation of left ventricular wall motion evaluated from the apical four-chamber view. Displacement of the left ventricular free wall and septum is simultaneously tracked in multiple points. A' , Late (atrial) diastolic velocity; *bpm*, beats per minute; E' , early diastolic velocity; *IVC*, isovolumic contraction period; *IVR*, isovolumic relaxation period; *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle; S' , systolic velocity.

velocities at the two points (V_1 and V_2 , respectively), the fluid density (for blood, $\rho = 1060$ kg/liter), and the velocity-dependent viscous friction according to the following equation:

$$\Delta P = \underbrace{\frac{1}{2}\rho(V_2^2 - V_1^2)}_{\text{convective acceleration}} + \underbrace{\rho \int_1^2 \frac{d\vec{V}}{dt} d\vec{s}}_{\text{flow acceleration}} + \underbrace{R(\vec{V})}_{\text{viscous friction}}$$

For most clinical applications of the Bernoulli equation, the convective acceleration component of the formula is considered the most significant. After combining ρ for blood with conversion factors to mm Hg and velocity to m/sec, the coefficient calculates out to 3.98. In most clinical applications this factor is rounded to 4.0. The second term of the equation, flow acceleration, represents the pressure drop generated by flow acceleration. This phenomenon, however, is important only during a very brief period at the rapid acceleration phase when there is a lag between the velocity and the pressure curves. During that time period, the pressure gradient is not considered clinically important. The third term represents the force necessary to overcome viscous friction. When considering pressure drops across a discrete orifice, viscous friction becomes negligible. Hence, for most clinical applications the formula is simplified based on the following assumptions: (1) the velocity proximal to the obstruction (V_1) is assumed to be negligible compared with the velocity just distal to the obstruction (V_2); (2) in most clinical situations, peak flow acceleration occurs in early systole when the pressure gradient is irrelevant and can be ignored; and (3) viscous friction is assumed to be trivial. The Bernoulli equation can therefore be simplified: $\Delta P = 4(V_2)^2$. This formula has been shown to be valid in in vitro flow models⁷⁸ and in various clinical settings.⁷⁹ However, the assumptions that govern the use of the simplified Bernoulli equation may not always be correct. For example, in long-segment narrowing such as a

Blalock-Taussig shunt, ignoring the viscous friction term of the Bernoulli equation may lead to significant underestimation of the pressure drop. The limitations and pitfalls that can potentially lead to errors in estimation of pressure gradients have been reviewed elsewhere.^{1,11}

Safety and Complications

Because of the widespread use of echocardiography in the diagnosis and monitoring of children with suspected heart disease, safety of the technique is of prime importance. This is particularly relevant in fetal echocardiography where fetuses may be exposed to ultrasound energy early in gestation. To date, no reports on adverse effects from diagnostic ultrasound have been reported. Physicians involved with diagnostic ultrasound must be aware that ultrasound is a form of mechanical energy that under certain conditions can cause biological damage to exposed tissue. This damage can result from conversion of mechanical energy to heat or from creation of gaseous microcavitations. Thus far, it appears that biological damage has been observed only in nonclinical laboratory conditions. The American Institute of Ultrasound in Medicine stated that “no confirmed biologic effects on patients or instrument operator caused by exposure at intensities typical of present diagnostic ultrasound instruments have ever been reported. Although the possibility exists that such biologic effects may be identified in the future, current data indicate that the benefits to patients of the prudent use of diagnostic ultrasound outweigh the risks, if any, that may be present.”⁸⁰

MAGNETIC RESONANCE IMAGING

Cardiovascular MRI is a sophisticated noninvasive imaging modality that overcomes many of the limitations of echocardiography and cardiac catheterization. High-resolution static and dynamic images of the heart,

blood vessels, and other thoracic structures are obtained regardless of body size and acoustic barriers. Moreover, cardiovascular MRI provides additional unique information that is not made available by other imaging techniques. As a result of the rapid technologic evolution in computer sciences, electronics, and engineering over the past decade, cardiovascular MRI has evolved from a technique that produced several static images in an hour-long examination to a modality capable of real-time imaging,^{81,82} succinct dynamic three-dimensional visualization of cardiovascular anatomy,⁸³ imaging of the fetus,⁸⁴ and accurate quantification of blood flow⁸⁵ and myocardial function.⁸⁶ These capabilities have greatly expanded the role of cardiovascular MRI in preoperative and postoperative evaluation of infants, children, and adults with CHD.

Magnetic Resonance Imaging Techniques and Their Clinical Applications

In MRI, magnetic fields and radiofrequency energy are used to stimulate hydrogen nuclei in selected regions of the body to emit radiofrequency waves that are then used to construct images. As with other cardiovascular imaging modalities, a thorough understanding of the underlying imaging physics enhances the quality and interpretation of the diagnostic data. This section provides a practical introduction to cardiovascular MRI; a more detailed discussion can be found in other sources.^{87,88}

To produce an image, the patient is first placed inside the scanner, which applies a static high-strength magnetic field. Most clinical scanners use static magnetic field strengths ranging from 0.5 tesla (T) to 3 T (1 tesla = 10,000 gauss [G]; the strength of earth's magnetic field at its surface is approximately 0.5 G). Higher magnetic field strengths are used mostly in research scanners. Once positioned within the scanner, a section of the patient's body is then excited using a radiofrequency pulse, and an echo is formed by means of a second radiofrequency pulse (spin echo) and/or gradient pulses (gradient echo). The signal from the echo is then processed by Fourier transformation and the data are used to fill a line of matrix from which the image is generated.

Cardiac and Respiratory Gating

The heart, blood, and blood vessels are in relatively rapid motion compared with other body structures. Although the speed of MRI continues to improve, standard techniques are too slow to image the heart in real time with adequate spatial and temporal resolution for most applications. Rather, an image at a particular point during the cardiac cycle is built up from data acquired over multiple cardiac cycles. Consequently, synchronization with the cardiac cycle is required to "return" to the same point in the cycle and effectively freeze cardiac motion. Imaging may be synchronized or "gated" with a pulse oxymetry trace (so-called peripheral gating) or, more optimally, with a high-quality electrocardiogram signal. Because images are constructed over multiple cardiac

cycles, respiratory motion can degrade image quality. One approach to minimizing respiratory artifacts is to have the patient hold his or her breath during image acquisition. Although this solution is often effective, it cannot be used in patients who are too young or ill to cooperate. In such cases, respiratory motion compensation can be achieved by synchronizing image data acquisition to the respiratory as well as the cardiac cycle. Respiratory motion can be tracked either by a bellows device placed around the body or by MRI navigator echoes that concurrently image the position of the diaphragm or heart. The principal limitation of respiratory gating is that it substantially prolongs scan times because image data are accepted during only a portion of the respiratory cycle. A final strategy to minimize respiratory motion artifacts is to acquire multiple images at the same location and average them, thereby minimizing variations due to respiration. As expected, the disadvantage of this approach is again increased scan time.

This discussion highlights the need for more rapid high-quality MRI techniques that will obviate the need for cardiac gating and respiratory motion compensation. Recent advances in gradient coil performance and parallel acquisition methods have achieved this goal and have become widely available in the clinical arena.⁸⁹⁻⁹³

Cardiovascular MRI examination is performed by repeatedly selecting a pulse sequence, prescribing an imaging location, and acquiring the image data to address specific clinical questions.⁹⁴ The pulse sequence specifies how the magnetic field gradients and radiofrequency pulses are applied and read during image acquisition. [Table 106-1](#) summarizes the features of some of the common cardiovascular MRI sequences used in clinical practice. In general, there are two major categories of pulse sequences—spin echo and gradient echo (see [Table 106-1](#)). Spin echo sequences are characterized by applying a radiofrequency pulse that tips hydrogen protons by 90 degrees, followed by a second, 180-degree pulse, and they are usually used to generate images in which flowing blood appears black. Gradient echo sequences apply radiofrequency pulses that are less than 90 degrees (usually 15 to 60 degrees), are faster than spin echo sequences, and are usually used to generate images in which flowing blood appears white. Adding preparatory pulses that alter tissue contrast can often modify a particular pulse sequence. In addition, there are numerous user-selectable imaging parameters that affect tissue contrast, image quality, and temporal and spatial resolution. The numerous imaging techniques and parameters to choose from allow the operator to adjust image contrast for optimal anatomic definition and detection of abnormal tissue. They also provide the capability for sophisticated functional assessment. The following section reviews the more common cardiovascular MRI techniques with a focus on their clinical usefulness.

Anatomic Imaging and Tissue Characteristics

Spin echo pulse sequences are usually used to produce images in which flowing blood has low signal intensity and appears dark ("black blood" imaging). Other tissues

TABLE 106-1 Summary of MRI Techniques

Technique	ECG Triggering	Appearance of Blood Flow	Dynamic (Cine*) vs. Static†	Clinical Application
I. Spin Echo				
Standard spin echo	Yes	Dark	Static	Anatomy, tissue characterization
Fast spin echo with double-inversion recovery	Yes	Dark	Static	Anatomy, tissue characterization, faster image acquisition relative to standard spin echo
II. Gradient Echo				
Segmented k-space fast gradient echo or steady-state free precession	Yes	Bright	Dynamic	Anatomy, ventricular function, blood flow imaging
Phase contrast	Yes	Bright	Dynamic	Flow quantification and characterization
Tagging	Yes	Bright	Dynamic	Analysis of myocardial mechanics and flow
Gadolinium-enhanced three-dimensional MRA	No	Bright	Static	Three-dimensional anatomic data set
MR fluoroscopy	No	Bright	Dynamic	Anatomy, function, guidance of interventional procedures
Delayed enhancement	Yes	Intermediate	Static	Myocardial viability

*Cine: Multiple images are obtained throughout the cardiac cycle in each anatomic location. The stacked images are then displayed on a computer screen in a cine-loop format.

†Static: A single image is obtained in each anatomic location.

ECG, Electrocardiography; MR, magnetic resonance; MRA, magnetic resonance angiography.

appear as varying shades of gray. Although cardiac-gated spin echo sequences produce only one image per location and thus provide only static anatomic information, their advantages include high spatial resolution, excellent blood-myocardium contrast, and decreased artifact from metallic biomedical implants (e.g., sternal wires, stents, prosthetic valves). Spin echo sequences are also easily modified to alter tissue contrast and characterize abnormal structures. Their clinical uses include evaluation for arrhythmogenic right ventricular cardiomyopathy,⁹⁵ cardiac tumors,⁹⁶⁻⁹⁸ constrictive pericardial disease,⁹⁹ vessel wall abnormalities,¹⁰⁰ trachea and mainstem bronchi,¹⁰¹ and thoracic masses (Fig. 106-12).¹⁰² Fast (turbo) spin echo sequences allow one location to be imaged rapidly enough for the patient to breath-hold (10 to 15 seconds). A double-inversion preparatory pulse is usually applied to suppress the blood signal,¹⁰³ and an additional inversion pulse may be applied to suppress fat signal.

Cine Magnetic Resonance Imaging

Cardiac-gated gradient echo sequences can be used to produce multiple images over the cardiac cycle in each anatomic location. These images can then be displayed in a cine-loop format to demonstrate the motion of the heart and vasculature over the cardiac cycle. On such cine MR images, flowing blood produces a bright signal, and the myocardium and vessel wall are relatively dark ("bright-blood" imaging) (Fig. 106-13). The most commonly used cine MR technique is steady-state free precession cine MR sequences.^{104,105} This technique relies on the ratio of T2-to-T1 relaxation, which results in high contrast between the blood pool ($T2/T1 = 360/1200 =$

FIGURE 106-12 ■ Electrocardiographically triggered, breath-hold, proton density-weighted, fast spin echo with double-inversion recovery images showing severe coarctation of the descending aorta at the level of the diaphragm in a 5-year-old patient with Takayasu aortitis. Note the markedly thickened aortic wall with severe luminal narrowing on the axial plane image (arrows).

FIGURE 106-13 ■ Clinical applications of gradient echo cine magnetic resonance imaging. **A**, Electrocardiographically triggered breath-hold segmented k-space fast spoiled gradient echo multiphase sequence in a patient with severe coarctation of the aorta. The relatively long echo time allows for clear depiction of the dephasing jet in systole (*arrow*) indicating high-velocity turbulent flow. **B**, Axial plane electrocardiographically triggered steady-state free precession multiphase sequence in a patient with heterotaxy syndrome and single ventricle after a Fontan operation. Note the left-sided Fontan pathway (Fon) as well as the clear depiction of intracardiac anatomy. **C**, Systolic turbulent jet (*arrow*) in a patient with aortic valve stenosis. **D**, Diastolic turbulent jet (*arrow*) in a patient with aortic valve regurgitation. 0.3) and the myocardium ($T2/T1 = 57/880 = 0.085$), providing clear definition of cardiovascular structures. Image acquisition is short (4 to 10 seconds depending on heart rate) and is further shortened by parallel processing, permitting real-time magnetic resonance fluoroscopy.^{84,106-108}

Cine MRI is used to delineate cardiovascular anatomy and assess ventricular function. It is helpful for evaluating the systemic and pulmonary veins,¹⁰⁹ atrial and ventricular septa,¹¹⁰⁻¹¹² intracardiac baffles and pathways (e.g., after Fontan, Mustard, Senning, and Rastelli procedures),¹¹³ ventricular outflow tracts, ventricular-arterial conduits,¹¹⁴ pulmonary arteries, and the aorta. It is also

useful in identifying stenotic and regurgitant jets, which appear as dark signal voids (see Fig. 106-13). Myocardial tagging is a modification of cine MRI that allows for a sophisticated analysis of regional myocardial function (see Ventricular Function section, earlier).^{86,115}

Magnetic Resonance Imaging Assessment of Ventricular Function

The principal MRI sequence used for evaluation of ventricular function is gradient echo cine MRI. An electrocardiographically triggered segmented k-space fast (also termed *turbo*) gradient recall echo sequence was used

extensively during the 1990s, and its accuracy and reproducibility in measuring left and right ventricular volumes, mass, and ejection fraction have been extensively validated.¹¹⁶⁻¹¹⁸ Since the early 2000s, steady-state free precession cine MR has replaced other gradient echo techniques. This sequence has been shown to provide a sharper contrast between the blood pool and the myocardium and to reduce motion-induced blurring during systole.^{89,119,120}

Quantitative evaluation of ventricular function is achieved by obtaining a series of contiguous cine MRI slabs that cover the ventricles in short-axis view (Fig. 106-14).^{82,86,121,122} By tracing the blood-endocardium boundary, the slab's volume is calculated as the product of its cross-sectional area and thickness (which is prescribed by the operator). Ventricular volume is then determined by summation of the volumes of all slabs. The process can be repeated for each frame in the cardiac cycle to obtain a continuous time-volume loop, or it can be performed only on a diastolic and a systolic frame to calculate diastolic and systolic volumes. From these data, left and right ventricular ejection fractions and stroke volumes can be calculated. Because the patient's heart rate at the time of image acquisition is known, left and right ventricular output can be calculated. Ventricular mass is calculated by tracing the epicardial borders, subtracting the endocardial volumes, and multiplying the resultant muscle volume by the specific gravity of the

myocardium (1.05 g/mm^3). Most manufacturers of MRI scanners and some third-party companies offer software packages that automatically perform these calculations. Development of algorithms for automatic border detection has facilitated the application of these techniques, but further refinements are required to improve its accuracy.¹²³ Because of the accurate spatial and temporal registration of data, MRI measurements of chamber dimensions have become the accepted reference standard to which other methods are compared.^{124,125} For example, Bellenger and colleagues measured left ventricular volumes in 64 patients with dilated cardiomyopathy.¹²⁶ They reported an intraobserver variability of $2.4\% \pm 2.5\%$, interobserver variability of $5.1\% \pm 3.7\%$, and interstudy variability (repeat MRI examinations) of $2.9\% \pm 1.2\%$. In patients with normal and dilated right ventricles, Mooij and coworkers reported interobserver intraclass correlation coefficients of 0.977 for right ventricular end-diastolic volume, 0.989 for left ventricular end-diastolic volume, 0.947 for right ventricular stroke volume, 0.973 for left ventricular stroke volume, and 0.789 and 0.81 for right and left ventricular ejection fraction, respectively.¹²⁷

Steady-state free precession cine MRI is also used to evaluate regional wall motion abnormalities and segmental wall thickening.¹²⁸ Dobutamine stress MRI has been reported to be a useful test in adults with coronary artery disease,¹²⁹⁻¹³¹ and initial experience in pediatric patients is

encouraging.¹³² More recently, the use of an MRI-compatible supine cycle ergometer has been reported to allow assessment of ventricular function and valve regurgitation response to exercise.^{133,134}

Another approach to MRI evaluation of ventricular function and myocardial mechanics is to visualize and measure myocardial motion. This can be done by myocardial tagging,¹³⁵ velocity-encoded cine MRI, or feature-tracking cardiac MRI.¹³⁶ In myocardial tagging, with the use of a preparatory radiofrequency gradient echo pulse sequence such as spatial modulation of magnetization (SPAMM), the spin of the protons in selected parts of the image volume are flipped in such a way as to render them incapable of producing a signal. This results in stripes of signal void (dark stripes) across the image (Fig. 106-15). The grid or stripes are placed at the onset of the R wave and is followed by a gradient echo cine MRI sequence. As the myocardium moves during the cardiac cycle, the tags follow it and their rotation, translation, and deformation can be tracked, allowing for calculation of myocardial strain and strain rate.¹³⁷⁻¹⁴⁰ A recently described technique for the analysis of myocardial tagging data, harmonic phase imaging, shortens the analysis time because it does not require manual tracing of the tags.¹⁴¹ Despite extensive research on myocardial tagging, the technique has not gained general acceptance in routine clinical practice. More recently, use of feature tracking MRI has been reported in CHD patients with promising early results (Fig. 106-16).^{142,143} An advantage of feature tracking over myocardial tagging is that it can be performed on routinely acquired cine SSFP images, as opposed to the special image acquisitions required for tagging analysis.

Blood Flow Analysis

An ECG-gated velocity-encoded cine MRI (VEC MRI) sequence, a type of gradient echo sequence, can be used to measure blood flow velocity and quantify blood flow

rate.^{85,144} The VEC MRI technique is based on the principle that the signal from hydrogen nuclei (such as those in blood) flowing through specially designed magnetic field gradients accumulates a predictable phase shift that is proportional to its velocity. Multiple phase images are constructed across the cardiac cycle in which the voxel intensity or brightness is proportional to blood velocity within that voxel. Flow quantification is performed by placing an imaging slab across a blood vessel or through the area at question within the heart (Fig. 106-17A). The operator then determines whether flow velocity encoding is performed only perpendicular to the imaging plane (z-axis) or in other directions as well (x-axis and y-axis). The data are then analyzed off-line using specialized software. A region of interest (ROI) is defined by the operator around the lumen of the relevant vessel and the instantaneous mean velocity of each voxel is calculated (see Fig. 106-17B and C). Flow rate is calculated as the product of the mean velocities within the ROI and its cross-sectional area. Integration of the instantaneous flow rates over the cardiac cycle yields the stroke volume (see Fig. 106-17D). This technique has been shown by in vitro and in vivo studies to be accurate and reproducible.^{144,145} Cine phase contrast has been widely applied to measure systemic and pulmonary blood flow and their ratio, as well as flow in individual pulmonary arteries, across the mitral and tricuspid valves, across an atrial septal defect, in systemic and pulmonary veins and in other individual blood vessels. This technique also allows accurate quantification of regurgitation volume and fraction across any cardiac valve.¹⁴⁶ An example of an important application of this technique in CHD is the quantification of pulmonary regurgitation in patients who have undergone tetralogy of Fallot repair.¹⁴⁷ When flow encoding is performed in three spatial directions, multidimensional flow imaging and analysis can be accomplished by resolving the flow velocities and directions into flow vectors that can be viewed in cine-loop format (Fig. 106-18). This technique allows unique

FIGURE 106-16 ■ Magnetic resonance imaging evaluation of myocardial deformation using speckle-tracking analysis. Circumferential left ventricular myocardial velocity, strain, and strain rates are shown.

imaging of blood flow in five dimensions (x , y , and z spatial dimensions, velocity, and time).¹⁴⁸ It also allows quantitative analysis of flow dynamics, including the ability to calculate the shear stress exerted by the flowing blood on the vessel wall.¹⁴⁹

Contrast-Enhanced Magnetic Resonance Angiography

Another approach for improving the contrast between vascular and nonvascular structures is to administer an exogenous intravenous contrast agent, typically a gadolinium chelate, which dramatically shortens the T1 relaxation of blood, resulting in a bright signal on T1-weighted sequences. This method of angiography is less prone to flow-related artifacts than other MR techniques and has a short acquisition time. Contrast-enhanced magnetic resonance angiography (MRA) is usually performed without cardiac gating using a three-dimensional fast gradient echo acquisition lasting 15 to 30 seconds while the patient holds his or her breath.¹⁵⁰ The time delay between contrast administration and image acquisition determines the vascular territory illustrated, and several acquisitions can be performed. The entire procedure takes only a few minutes to perform and yields a high-contrast and high-resolution three-dimensional data set depicting all or part of the thorax. The three-dimensional data set can be navigated on dedicated workstations using various image display techniques, including rapid construction of intuitive three-dimensional models (Fig. 106-19). Unlike cine MRI, conventional contrast-enhanced MRA is not time resolved. However, with continued improvements in imaging speed, time-resolved MRA is now possible.¹⁵¹

MRA is ideally suited to elucidate the anatomy of the aorta and its branches, pulmonary arteries, pulmonary veins, and systemic veins.^{152,153} Although this technique is mostly used for imaging of extracardiac anatomy, we have found it useful in the evaluation of intra-atrial systemic and pulmonary baffles (such as in Mustard and Senning operations and after Fontan procedures), as well as for imaging of the outflow tracts (such as in repaired tetralogy of Fallot and the arterial switch operation). In addition, MRA clearly delineates the spatial relationships between vascular structures, the tracheobronchial tree, chest wall, spine, and other landmarks that may be useful for planning of interventional catheterization or surgical procedures.

Myocardial Ischemia and Viability

Although traditionally the diagnosis of myocardial ischemia has not been a focus of imaging in CHD, it clearly has relevance in patients who have congenital and acquired coronary abnormalities (e.g., anomalous origin of the left coronary artery, pulmonary atresia with intact ventricular septum, and Kawasaki disease). Moreover, myocardial ischemia is an important diagnostic challenge in patients postoperatively and in adults with CHD. Several MRI techniques for imaging the coronary arteries with sufficient resolution to detect stenotic lesions are now available.¹⁵⁴ However, the optimal approach and clinical usefulness will likely remain in evolution for the next several years. MRI techniques are also available for assessment of regional left ventricular myocardial perfusion.^{155,156} Typically, after a rapid intravenous gadolinium contrast injection, ultrafast, multislice imaging with an

FIGURE 106-17 ■ Quantitative assessment of pulmonary regurgitation by velocity-encoded cine magnetic resonance imaging (MRI) in a 26-year-old patient with repaired tetralogy of Fallot. **A**, An imaging plane is placed across the main pulmonary artery (MPA) (multiphase gradient echo cine MR). **B**, Magnitude image showing bright signal in the proximal MPA. **C**, The corresponding phase image contains the velocity and directional data. Using a computer workstation, a region of interest (*oval*) is placed around the MPA. **D**, The systolic flow-time integral (area under the curve above the baseline) yields the antegrade flow volume, and the diastolic flow-time integral (below the baseline) corresponds to the regurgitant flow volume. Regurgitation fraction is calculated as the ratio of retrograde (regurgitant volume) to antegrade volume. Ao, Aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

echo-planar pulse sequence is performed during a 20- to 25-second breath-hold to image the first pass of contrast through the myocardium (Fig. 106-20). The procedure can be repeated after administering a coronary vasodilator (e.g., adenosine or dipyridamole). Although MR perfusion imaging offers superior spatial resolution compared with nuclear cardiology techniques without the use of ionizing radiation, its widespread application has been limited by the need for time-intensive analysis and

insufficient clinical validation. Alternatively, cine MRI can be used to detect focal wall motion abnormalities with pharmacologic stress-induced ischemia. Several studies have demonstrated that for dobutamine stress studies, MRI compares favorably with transthoracic echocardiography, primarily as a result of its superior image quality.¹⁵⁷⁻¹⁵⁹ Finally, various MRI techniques have been used to assess myocardial viability. In particular, hyperenhanced myocardial regions observed 10 to 15

minutes after the administration of gadolinium contrast agents (termed *delayed myocardial enhancement*) are indicative of irreversible myocardial injury (Fig. 106-21).¹⁶⁰⁻¹⁶² Human studies assessing the usefulness of this technique have demonstrated its ability to detect scar tissue and other myocardial abnormalities in various types of acquired heart disease in adults.^{159,163-167} Although experience in patients with CHD is limited, several studies have demonstrated the ability of this technique to detect scar tissue in patients with tetralogy of Fallot, systemic right ventricle, endocardial fibroelastosis, and other conditions.^{156,168-171}

Indications for Cardiovascular Magnetic Resonance Imaging

The indications for cardiac MRI in patients with congenital and acquired pediatric heart disease are rapidly expanding. In general, the clinical reasons for a cardiac MRI examination may fall into one or more of the following three categories: (1) when transthoracic echocardiography is incapable of providing the required diagnostic information; (2) as an alternative to diagnostic cardiac catheterization with its associated discomfort, ionizing radiation exposure, contrast agent load, risks of morbidity and mortality, and high cost; and (3) for MRI's

FIGURE 106-21 ■ Assessment of myocardial viability in a patient with Kawasaki disease, giant coronary artery aneurysm, and large anterior myocardial infarction extending to the apex. unique capabilities such as tissue imaging, myocardial tagging, and vessel-specific flow quantification.

General Considerations

Detailed preexamination planning is crucial given the wide array of imaging sequences available and the often complex nature of the clinical, anatomic, and functional issues in patients with CHD.⁹⁴ The importance of a careful review of the patient's medical history—including details of all cardiovascular surgical procedures, interventional catheterizations, findings of previous diagnostic tests, and current clinical status—cannot be overemphasized. As is the case with echocardiography and cardiac catheterization, cardiovascular MRI examination of CHD is an interactive diagnostic procedure that requires on-line review and interpretation of the data by the supervising physician. The unpredictable nature of the anatomy and hemodynamics often requires adjustment of the examination protocol; modification of imaging planes; adding, deleting, or changing sequences; and adjustment of imaging parameters. Reliance on standardized protocols and post hoc reading alone in these patients might result in incomplete or even erroneous interpretation.

Sedation is often required in young patients who cannot cooperate with a cardiac MRI examination. Most patients younger than 5 or 6 years require sedation, some patients between age 6 and 10 years are capable of cooperation, and most children older than 10 years can undergo a cardiac MRI study without sedation provided their mental development is age appropriate and they are not claustrophobic. Anxiolysis with oral midazolam or other medications is helpful in patients with mild or moderate claustrophobia or other forms of anxiety.¹⁷² Screening for sedation need is part of the scheduling process for cardiac MRI, and consultation with the referring cardiologist and parents is advised. Both conscious sedation and general anesthesia have been successfully used in cardiac MRI. In our experience, advantages of general anesthesia include a better safety profile (secured airways and close monitoring by a pediatric anesthesiologist); ability to suspend respiration, leading to improved image quality and a shorter examination time; and control over duration of sedation.^{173,174} Disadvantages of this approach include a higher cost and disability of skilled anesthesia personnel. Other centers have successfully used different methods of sedation.¹⁷⁵⁻¹⁷⁷

Safety and Complications

Standard clinical imaging scanners present no known hazards to biological materials. Three different magnetic fields are used by such magnets: the relatively large static magnetic field, smaller but rapidly varying magnetic fields secondary to the magnetic field gradients, and radio-frequency pulses. Guidelines set by the U.S. Food and Drug Administration keep the strength of these fields well below levels that could cause significant biological effects. Animal studies evaluating the influence of static magnetic fields have not demonstrated significant biological effects for fields of up to 2 T.¹⁷⁸ Millions of patients have undergone MRI studies without any noticeable immediate or

long-term sequelae. Pregnancy is presently a relative contraindication to MRI studies, although the magnetic field levels used in clinical imagers have no known effects on the embryo. Many women have undergone MRI during all trimesters of pregnancy without reported ill effect on the mother, fetus, or resultant infant. When maternal and fetal health considerations require diagnostic studies, MRI is preferable to methods that use x-rays, such as computed tomography (CT) or angiography.

Implanted metallic objects are of particular concern, because they could potentially undergo undesirable torquing movements if the magnetic field were sufficiently strong and if they contained sufficient ferromagnetic material. Fortunately, surgical clips and sternotomy wires implanted in the chest and abdomen are typically only weakly ferromagnetic. Furthermore, these devices quickly become immobilized by surrounding fibrous tissue, so MRI can be safely performed in patients with these implants.¹⁷⁹ The wires and clips, however, may cause image artifact. Similarly, patients with implanted intravascular coils, stents, and occluding devices can be imaged by MRI once the implants are believed to be immobile. Many centers choose to avoid exposing these patients to MRI for an arbitrarily chosen period of time after implantation (usually for several weeks), but such practice is not supported by conclusive published data. A decision to perform MRI examination shortly after cardiac surgery or implantation of a biomedical device must weigh the risk-to-benefit ratio for the individual patient.^{179,180}

A number of devices are considered either relative or absolute contraindications to MRI.^{179,180} Presence of an intracranial, intraocular, or intracochlear metallic object is considered a contraindication to MRI. The presence of a cardiac pacemaker is also considered a strong relative contraindication to MRI,¹⁸¹ although some reports have suggested that scanning patients who have modern pacemakers may be possible.¹⁸²⁻¹⁸⁵

Because MRI scanners attract ferromagnetic objects, extreme caution should be used in approaching magnets with objects containing iron or other ferromagnetic materials. Only specially designed MRI-compatible physiologic monitoring equipment should be used in conjunction with MRI studies. There have been several reported cases of patient burns resulting from the use of MRI-incompatible pulse oximeters and electrocardiographic monitoring devices.

SUMMARY

Accurate diagnosis of CHD can be accomplished by the judicious use of a variety of modalities. Echocardiography has assumed a leading role as the primary diagnostic tool in pediatric cardiology because of its noninvasive nature and its ability to provide comprehensive accurate diagnostic information in real time, in various clinical settings, and at a reasonable cost. Cardiovascular MRI is rapidly becoming an important diagnostic tool in pediatric cardiology because of its ability to provide anatomic and functional information that cannot be obtained by echocardiography or, in some cases, by catheterization.

INTRODUCTION AND OVERVIEW

Catheterization in the field of congenital cardiology continues to improve understanding of disease and expand options for therapy. Diagnostic information previously obtained exclusively through catheterization is now routinely acquired through use of a host of diverse and highly sophisticated, noninvasive diagnostic imaging modalities. Invasive hemodynamic measurement and angiographic assessment, however, remain a mainstay in the comprehensive evaluation of the patient with complex heart disease. Furthermore, the interventional role of cardiac catheterization in the management of congenital heart disease continues to evolve, and in conjunction with surgical improvements, presents expanding opportunities for therapeutic intervention. Thus, the catheterization laboratory is increasingly like an operative suite, and in many cases of “hybrid” suites, it incorporates functions of a more traditional cardiac operating room.

Ongoing advances in transcatheter technology ensure that the historical border zone between transcatheter and

open therapies will continue to shift and likely broaden. Thus, the team of cardiac surgeons and cardiologists who deal with congenital heart disease will benefit from a contemporary awareness of the capabilities and limitations of their partners' work. What follows is a brief summary of the basic hemodynamic and angiographic information acquired through cardiac catheterization and a rough sketch of the currently practiced procedures. The remainder of the chapter provides a survey of the current state of transcatheter therapies, from valvuloplasty to valve replacement, including angioplasty and defect closure using implantable devices. It also provides an overview of the experience to date with fetal cardiac intervention.

ROLE OF DIAGNOSTIC CATHETERIZATION

A primary role of the catheterizer, since the earliest days of invasive physiologic assessment of congenital heart disease, has been to safely obtain the data necessary to

formulate a complete and accurate anatomic and hemodynamic understanding of the patient. This role as an investigator of physiology remains a defining role of the best invasive cardiologists; a thorough diagnostic catheterization constitutes a valuable part of almost all studies performed, even in the current era of intervention. An equally important role is to assist in planning management and to perform necessary transcatheter interventions as indicated, part of the integrated care of the patient with congenital disease. The ideal care of the most anatomically complex patients will likely require an orchestrated series of both open surgical and catheter-based procedures to achieve good, long-term, functional outcomes. A third, and more recent, role of the interventional cardiologist is to provide definitive therapy via a minimally invasive route, for some highly selected cardiac defects, as an alternative to surgery.

For decades, traditional biplane angiographic imaging constituted an important component of anatomic assessment of congenital heart disease. Expertise in acquisition and interpretation of these images secured the role of angiography in the preoperative investigation of patients with most major anatomic defects. The enormous volume of information provided by this modality has, fortunately, been exhaustively catalogued by Freedom and colleagues.¹ Preoperative anatomic information is now routinely and comprehensively acquired by noninvasive imaging modalities, primarily echocardiography, and increasingly, magnetic resonance imaging (MRI) or computed tomography (CT), as discussed in [Chapter 106](#). Valvar anatomy is beautifully displayed using transesophageal or three-dimensional echocardiography; ventricular volumes and function are quantified using MRI. Vascular abnormalities, such as aortic arch anomalies, or the complex venous patterns in heterotaxy syndrome, can similarly be well rendered through CT or MRI reconstruction.² These modalities will no doubt continue to undergo improvements in ease of acquisition, image resolution, and post-processing capabilities, likely avoiding the need for diagnostic angiography in all but rare cases. With currently available technology, vascular beds in which angiography remains the gold standard include pulmonary vessels beyond the hilum, and the coronary arterial bed, particularly in younger and smaller patients with highly atypical variants ([Fig. 107-1](#)).³

With the changing, and increasingly interventional, role of catheterization, the need for integration of three-dimensional anatomic information into the procedure has driven the development of “overlay” technologies and transfer/display of non-angiographic imaging data into the catheterization laboratory. As a natural evolution, the techniques and technology to acquire three-dimensional angiographic data sets have developed and matured to the point of incorporation into clinical practice in many centers. For patients who may also have indications for direct hemodynamic measurement and are candidates for intervention, this alternative provides the advantage of giving the interventionalist highly directed, immediate, as-needed, anatomic information at the time of catheterization. This advantage obviously needs to be considered in the context of the associated radiation exposure but will certainly warrant the angiographic information in

FIGURE 107-1 ■ Right ventricular angiography in a neonate with pulmonary atresia and intact ventricular septum. Injection in the right ventricle opacifies the entire coronary artery system and documents right coronary ostial atresia.

some cases. The feasibility of MRI-guided cardiac catheterization has been shown, and MRI-guided interventions have been performed in experimental settings.^{4,5} To date, limitations have been posed by the availability of adequate MRI-compatible intravascular tools and by the processing speed of MRI systems, which lack the real-time feedback of fluoroscopy.

Much hemodynamic information can also be derived from echocardiography and MRI, as is discussed in great depth in [Chapter 106](#). In some cases, there is no substitute for directly measured pressures that must be obtained invasively. When the best possible estimate of pulmonary vascular resistance is critical—as in the case of (1) pulmonary hypertension, (2) pretransplant evaluation, or (3) preoperative risk assessment for single ventricle palliation—cardiac catheterization is performed despite the availability of other methods. Similarly, even with a myriad of noninvasive indicators of diastolic function, direct measurement of the end-diastolic pressure is not infrequently an indication for catheterization. In the case of both pulmonary vascular assessment and measurement of filling pressures, the catheterization procedure also provides the opportunity to perform maneuvers to understand physiologic responses to intervention, such as administration of nitric oxide, expansion of intravascular volume, infusion of inotropes, or manipulation of pacing parameters. Fortunately for the invasive cardiologist, cardiac catheterization is a highly interactive process, and so as observations are made, hypotheses can be tested, disruptions such as test occlusions can be imposed, or interventions can be undertaken.

For surgical patients, the operating surgeon ultimately decides whether the accuracy and completeness of preoperative diagnostics is sufficient to plan and proceed

with the operation with the best possible outcome expected. For patients with complex disease or those with atypical management, early and steady involvement of the surgeon in the preoperative evaluation, including the conduct of the catheterization, is invaluable. A firm grasp of the advantages and limitations of data gained through all available techniques is critical, as is the ability to resolve apparently conflicting findings and place the appropriate weight on specific measurements or interpretations.

Although a series of preoperative hemodynamic catheterizations have been a staple of management for single ventricle disease, it is increasingly argued that many of these studies may be of marginal benefit and may not warrant the risk of an invasive procedure and radiation exposure. Most clinically well patients with favorable findings of noninvasive evaluation are likely to undergo successful bidirectional Glenn operation, or even Fontan, without excess of morbidity and without the benefit of a preoperative catheterization.^{6,7} The role of hemodynamic catheterization in this setting is ultimately determined by the reliability of noninvasive imaging modalities, primarily echocardiography, to screen for and accurately identify potential problems, such as pulmonary arterial distortion or arch obstruction, which should be addressed either in the catheterization laboratory or at the time of operation. Also, it is incumbent on the catheterizer to demonstrate the usefulness of some interventions that might occur at preoperative catheterization. The routine scheduling of catheterization before a Glenn or Fontan procedure is likely to receive increasing scrutiny in the future, and the added value of these studies will need to be defended.

HEMODYNAMIC ASSESSMENT

A full hemodynamic data set allows estimation of systemic and pulmonary blood flow, measurement of intracardiac and intravascular pressures with evaluation of pathologic gradients, and calculation of systemic and pulmonary vascular resistances. Two important vulnerabilities of traditional hemodynamic assessment in the catheterization laboratory are the designation of oxygen consumption, which is most often assumed, and the assumption of a steady state. Both of these limitations are more pronounced when dealing with more extreme or labile circulations. Ideally, the primary hemodynamic data can be obtained during catheterization under conditions that approximate each patient's baseline condition. The routine use of general anesthetic may pose some difficulty in this regard.

Flows

Systemic blood flow, or cardiac index, is commonly estimated either by a thermodilution technique or by using the Fick method. Calculation of flow using the Fick method is based on the principle that the total uptake (or release) of a substance by an organ is the product of blood flow to that organ and the difference between the concentrations of an indicator substance in the arteries and

veins leading into and out of that organ. When calculating the systemic blood flow, the whole of the systemic tissues are considered the organ, and oxygen is considered the indicator. By measuring the hemoglobin concentration, the percent oxygen saturation of hemoglobin, and the partial pressure of oxygen in a given sample of blood, the oxygen content can be calculated. The oxygen contents of aortic and mixed systemic venous blood samples serve as the necessary concentrations of indicator, and the patient's oxygen consumption represents the total uptake of indicator in a given unit of time (1 minute). The systemic blood flow, or cardiac index (Qs), can be calculated according to the following equation:

$$Q_s \text{ (L/min/m}^2\text{)} = \frac{\text{O}_2 \text{ consumption (mL O}_2\text{/min/m}^2\text{)}}{\text{systemic arterial - systemic venous O}_2 \text{ content (mL O}_2\text{/dL)} \times 10}$$

Although methods exist for measuring oxygen consumption during catheterization, most catheterization laboratories assume a level of oxygen consumption based on the patient's age, sex, and heart rate.

Pulmonary blood flow can be similarly calculated by calculating the oxygen content of pulmonary arterial and venous blood. With the systemic and pulmonary blood flow rates in hand, various shunts can be calculated, and the ratio of pulmonary to systemic blood flow, or Qp:Qs, can be determined. A rapid bedside calculation of Qp:Qs can be obtained by simply using the following equation:

$$Q_p : Q_s = \frac{\text{aortic saturation - mixed venous saturation}}{\text{pulmonary venous - pulmonary arterial saturation}}$$

Pressures

At catheterization, pressure measurements are obtained through fluid-filled catheters, which are vulnerable to various errors, ranging from an inappropriate zero level, to catheter entrapment with waveform distortion. Ideal catheters for pressure transduction provide free communication between the environment external to the catheter tip and the lumen of the catheter. Thus, larger-bore catheters, or catheters with multiple end or side holes, yield the most accurate depiction of the intracardiac waveform. A complete set of pressure measurements includes pressure waveforms recorded in all cardiac chambers and great vessels. When the left atrium is not entered directly, a pulmonary capillary wedge tracing is recorded in lieu of a left atrial trace. Systolic and diastolic pressures are noted in arterial vessels, whereas mean pressures are commonly noted in atrial or venous tracings. In the ventricle, the systolic and end-diastolic pressures are specified. Gradients can be documented by single catheter pullback or by simultaneous recordings in adjacent chambers or vessels using multilumen catheters or multiple catheters. When interpreting pressure gradients to determine the severity of obstructive lesions, the general principle of Ohm's law as it applies to hemodynamic variables must be considered, and the gradient should be considered in the context of the flow across the lesion.

Resistances

Having measured pressures and calculated flows, the resistance across a vascular bed can be calculated by relating the mean pressure change (ΔP) across that vascular bed to its flow. In the following equation,

$$R = \frac{\Delta P}{Q}$$

will thus be applied as

$$PVR = \frac{TPG}{Q_p},$$

where TPG is the transpulmonary gradient, which is equal to the mean pulmonary artery pressure minus mean pulmonary venous pressure, and PVR is pulmonary vascular resistance. The pressures are measured in millimeters of mercury (mm Hg), and flows are typically indexed and expressed in liter/min/m². Thus resistance is commonly expressed as mm Hg/liter/min/m², or indexed Wood units.

SEDATION AND ANESTHESIA

There is wide institutional variability in approaches to sedation for catheterization.⁸ Stimuli associated with catheterization include local pain related to percutaneous placement of access sheaths and more visceral pain related to intracardiac or intravascular manipulation and interventions. Provoked ectopy or arrhythmia, even if hemodynamically stable, may be disturbing to awake patients. Older, cooperative children without major hemodynamic compromise can, for the most part, undergo a routine catheterization safely and comfortably with conscious sedation and a spontaneous airway. In preparation for the procedure, oral benzodiazepines can be administered as anxiolytics before placing an intravenous line. Once intravenous access is established, a combination of benzodiazepines and opioids works well for most children who undergo catheterization without general anesthesia. Bolus doses of these drugs may be administered over the course of the procedure, or a continuous infusion may be preferable, depending on the nature and duration of the case. Alternative agents that have been used successfully with appropriate oversight are ketamine in conjunction with midazolam, and propofol infusion.

In the current era, general inhalational anesthetic is administered for most pediatric cases, to minimize the potential for patient discomfort. Some interventional cases warrant general anesthetic almost regardless of the tolerance or cooperativity of the patient, because of the anticipated duration of the procedure, high-risk nature of the intervention, necessity of patient immobility, and/or the need for both airway and hemodynamic control. Most infants and young children who are likely to be undergoing interventional procedures are most safely catheterized under general anesthesia. In addition, individuals who require uncomfortable additional impositions, such as placement of a transesophageal

echocardiographic probe for monitoring device closure of atrial septal defects (ASDs), or placement of internal jugular or subclavian catheters, are less likely to be distressed if under a general anesthetic.

Very rarely, the induction of general anesthesia or use of inhalational anesthetic may, in and of itself, be destabilizing, as can be the case in children with left ventricular (LV) outflow obstruction and/or coronary compromise, or those with severe restrictive physiology. Patients with severe heart failure who rely on endogenous catecholamine levels for maintenance of circulation can also be at risk with typical anesthetic induction techniques. Consultation with, and anticipatory inclusion of, members of a dedicated cardiac anesthesia team before catheterization serves the best interests of the patients and their caregivers and contributes to successful completion of the procedure.

VASCULAR ACCESS

Standard Arterial and Venous Access

For most catheterization procedures, intravascular access is established and maintained in both an artery and a vein. Even when a single venous catheter may provide access for a full hemodynamic data set, an arterial catheter is often placed for continuous intraprocedural monitoring. Placement of an arterial line in these cases should be weighed against the risk of compromised postprocedural perfusion of the extremity. Highly focused cases in stable, healthy subjects (e.g., ASD closure, pulmonary valvuloplasty) are usually performed with only a venous line, as are many pulmonary hypertension studies and routine cardiac biopsies. In some emergent clinical situations, when there is a premium on speed of intervention, the case should not be delayed while placing “elective” access, but rather the catheterizer should be creative about the most expedient access possible to complete the procedure.

Vascular access is typically established in the femoral vessels, as the consistent anatomy, superficial course, and relative sizes of these vessels allow straightforward percutaneous entry. The side-by-side placement of femoral venous and arterial lines allows the operator to stand over a well-circumscribed field that can easily be kept sterile and allows the patient to be continuously audited for catheter displacement or bleeding. Given the placement of standard anteroposterior and lateral cameras in a biplane lab, the femoral sites are also the most ergonomically favorable. Approach to the heart via the femoral vein and the inferior vena cava allows entry to almost all necessary catheter sites, including complex transseptal courses that can be difficult from a superior approach. At the conclusion of the procedure, catheter removal and control of the vessels in the groin with manual compression is relatively easy, and the procedure is well tolerated by individuals of all ages. In pediatric catheterization, manual compression is most often applied to achieve hemostasis. In larger patients, especially those who have had large caliber sheaths in the femoral vessels, the use of percutaneous site closure systems can

significantly reduce the time to hemostasis and the risk of late rebleeding.

Alternate Routes of Access

For some catheterizations, alternative sites of access are electively chosen. In newborns, part or all of the study can often be carried out from the umbilical vessels. The umbilical vein approach is ideal for balloon atrial septostomy in infants with transposition of the great arteries, and the use of this access site spares the femoral vein from potential injury by the relatively large sheath. Compared with standard femoral access, umbilical access makes complex venous catheter manipulation more difficult, and greater attention must be paid to maintaining sheath positioning. Only simple manipulation of the arterial catheter is possible, and catheter exchange should be limited, as the tortuous abdominal course from the umbilical artery to the aorta can predispose the patient to arterial trauma.

Access from the jugular or subclavian vein may be planned in some cases because of anatomic factors, such as the presence of a Glenn anastomosis, when there is typically no other navigable pathway to the pulmonary arteries. Non-femoral sites may also be electively chosen in smaller patients who require larger access sheaths, for example, for device delivery. The jugular or subclavian vein is typically larger than the femoral vein, and if both communicate in a usual way with the right atrium, these brachiocephalic vessels may be an alternative, or even preferred, route. In rare cases, transhepatic access is electively chosen to provide a short, direct course to the atrial septum or pulmonary veins for defect closure or creation, or for pulmonary venous sampling or interventions.

Increasingly, alternative (to the femoral vessels) access is used out of necessity, because the femoral vein or artery is occluded. Brachiocephalic veins may be used primarily when prior procedures or indwelling catheters have caused vascular compromise and loss of the femoral venous access. Similarly, a percutaneous transhepatic route can be used safely, even in infants.⁹ Importantly, we and others have found that in many cases of suspected or known loss of femoral vessels, taking a more aggressive approach with the use of specialized guidewires, catheters, and fluoroscopic guidance will often allow reestablishment or enlargement of femoral vascular continuity with the central circulation.¹⁰ This enables not only cardiac catheterization from these routes but placement of long-term indwelling lines. Long-term patency remains an issue and may be improved with placement of intravascular stents or antithrombotic therapy.

The cardiac surgeon may be asked to assist in a number of ways to facilitate the access for a catheterization procedure. In a backup capacity, surgical cutdown may be necessary when attempts at necessary percutaneous access fail. Most interventionalists have limited experience with these procedures and will require the assistance of a surgeon. This may involve cutdown on extremity vessels (femoral, radial, axillary) or on neck vessels. Surgical cutdown on the carotid artery can greatly facilitate aortic valve dilation in small infants, allowing for larger-caliber dilating balloons to be easily introduced and often for

easier retrograde passage through a highly obstructed valve.

Beyond extremity or neck cutdowns, the surgeon and interventionalist can work together to conduct procedures with a variety of alternative surgical exposures. A limited thoracotomy can enable a better angle of approach to the right atrium for device closure of large ASD, or a more controlled site of direct LV access for aortic valve delivery, or external control/reduction and visualization of the right ventricular (RV) outflow tract during placement of a transcatheter pulmonary valve. The hybrid stage I procedure is performed with open chest access to deliver the ductal stent directly from the main pulmonary artery and perform pulmonary arterial bands simultaneously. With the increasing use of catheter-based devices, many of which require relatively large delivery systems, surgical access to large intrathoracic vessels or even direct cardiac access, will likely become a more frequent opportunity for creative interaction between interventionalist and surgeon.

INTERVENTIONS

Balloon Atrial Septostomy

Rashkind and Miller reported the first balloon atrial septostomy in 1966, describing a new means of palliating the cyanotic child with transposition of the great arteries and launching the field of interventional congenital catheterization.¹¹ In the era of neonatal arterial switch operation, early postnatal septostomy allows preoperative stabilization, reduces the need for prostaglandin infusion (with its attendant morbidities), and can be lifesaving in neonates who lack favorable mixing. The potential for a causal relationship between preoperative septostomy and brain injury in neonates with transposition remains a matter of open debate.^{12,13}

There has been remarkably little change in the technique or equipment used since the first description of septostomy. A balloon-tipped catheter, introduced via the umbilical or femoral vein, is positioned in the left atrium through the patent foramen ovale and is rapidly accelerated across the septum into the right atrium (Fig. 107-2). Although traditionally performed under fluoroscopic guidance, results are equally satisfactory with echocardiographic guidance at the bedside in the intensive care unit, with only rare complications.¹⁴ Once access is established, the procedure takes only a few minutes, and immediate improvement in systemic saturations can be expected. Newborns now rarely need to be transported to and from the catheterization laboratory for the procedure.

Emergent septostomy can be lifesaving in the neonate with hypoplastic left heart syndrome (HLHS) and restrictive atrial septum, one of the few truly emergent call cases for the interventionalist. These patients are often deeply cyanotic and require ongoing hemodynamic support when they arrive in the catheterization laboratory, despite prostaglandin infusion. Cardiologists and surgeons who care for these infants increasingly recognize the benefit of immediate postnatal left atrial decompression to improve survival.¹⁵ When a small preexisting defect can

FIGURE 107-2 ■ The mode of imaging during balloon atrial septostomy depends largely on the location of the procedure. **A**, Echocardiographic image of the saline-filled septostomy balloon in the left atrium. **B**, Fluoroscopic visualization of the contrast-filled septostomy balloon in the left atrium over a wire course into a left pulmonary vein.

be crossed, a standard pull-through septostomy can be effective acutely, but restenosis occurs almost universally.¹⁶ Creation of an iatrogenic atrial defect by transseptal puncture, followed by static balloon dilation or stent placement (or both), may be more effective and durable but is associated with a known incidence of inadvertent cardiac perforation.^{17,18} This aggressive catheter-based approach may improve survival among patients with this disease, and fetal intervention may, in some cases, avoid catastrophic neonatal presentation altogether.¹⁹

Valve Interventions

The anatomic substrate of valvar obstruction in semilunar valve disease is most commonly commissural fusion, which lends itself to relief by “splitting” of the commissure, which can be accomplished effectively, perhaps not elegantly, by balloon valvotomy. Transcatheter balloon valvotomy is now primary therapy, in many centers, for pediatric valvar pulmonary and aortic stenosis, with good results. With regard to semilunar valves, most patients respond favorably to this simple mechanical enlargement of the effective orifice. In contrast, mechanisms of obstruction in congenital atrioventricular valve disease are less well understood and likely much more complex anatomically. Thus, mitral and tricuspid valve dilations are practiced relatively infrequently and with mixed results, highly dependent on the underlying valve morphology. In fact, there is no published experience with a significant series of patients who have undergone tricuspid valve dilation in the catheterization laboratory.

Pulmonary Valvuloplasty

Since Kan and colleagues reported the first static balloon dilation of the pulmonary valve in 1982, this procedure has become a universally practiced treatment of isolated valvar pulmonary stenosis.²⁰ The typical indication for

intervention is RV hypertension at or near systemic levels. A number of dilating techniques have been applied with good results, and long-term follow-up information is available. The Valvuloplasty and Angioplasty of Congenital Anomalies (VACA) Registry investigators reported excellent results in a large group of pediatric patients with pulmonary stenosis, with 89% of patients achieving gradients of less than 35 mm Hg after the procedure.^{21,22} The use of markedly oversized balloons in an attempt to maximize gradient reduction risks significant pulmonary insufficiency, generally believed to be of little clinical consequence in the short term but increasingly recognized as a long-term morbidity.^{23,24} Experimental induction of RV outflow tract damage, and the clinical observation of increased pulmonary insufficiency after oversized balloon dilation, support the current practice of moderately oversizing the balloons, with balloon-to-annulus ratio limited to 1.4:1.^{21,25,26}

When the mechanism of obstruction is a highly dysplastic valve, such as that seen in patients with Noonan syndrome, results of balloon valvuloplasty are less predictable; these patients may require surgery for adequate gradient relief.²² Other types of arteriopathy, such as that seen in association with Williams syndrome, may similarly exhibit limited response to balloon valvuloplasty; it is often the case that contribution of supravulvar pulmonary stenosis to RV outflow obstruction is underestimated prior to direct measurement and attempted dilation.

Pulmonary valvuloplasty techniques developed in older children have been successfully applied to the neonate with critical pulmonary stenosis, and balloon dilation is now essentially standard for primary treatment in this population as well.^{27,28} The valve is crossed antegrade from the RV outflow tract with a floppy-tipped wire. In the presence of a patent ductus arteriosus, an antegrade wire course into the descending aorta facilitates balloon passage across even very highly obstructed valves, and valve dilation will typically allow

FIGURE 107-3 ■ Lateral images during radiofrequency perforation in pulmonary atresia, followed by balloon dilation of the valve. **A**, Contrast injection through a shaped end-hole catheter positioned in the right ventricular outflow tract just below the imperforate valve. **B**, The radiofrequency wire is advanced across the valve, using a wire loop passed retrograde from the aorta as a visual target. **C**, Subsequent balloon dilation of the valve is performed using a technique common to more routine critical pulmonary stenosis procedures.

discontinuation of the prostaglandins and result in definitive, nonsurgical therapy.

In some neonates with membranous pulmonary atresia and intact ventricular septum who are candidates for biventricular outcome, neonatal RV decompression can be accomplished percutaneously as a first step in management. An apparently atretic valve can be probed with a floppy-tipped wire, and, if truly imperforate, the valve can then be passed using a radiofrequency wire (Fig. 107-3).^{29,30} After the valve is crossed, serial balloon dilations can eliminate the valvar contribution to RV outflow obstruction, potentially with less resultant pulmonary regurgitation than would be acquired surgically, and allow some period of neonatal palliation prior to more definitive surgery. Establishment of sufficient pulmonary

blood flow through a Blalock-Taussig shunt or through maintenance of ductal patency is often still necessary, because of a prohibitively restrictive RV or persistent subvalvar obstruction.³¹

Aortic Valvuloplasty

When expanding the application of percutaneous valvuloplasty to aortic valve dilation, interventional cardiologists were presented with a number of new concerns. Intrinsic differences in the compliance characteristics of the stenotic aortic valve relative to that of the pulmonary valve required a unique determination of optimal balloon size. Identification of the ideal balloon-to-annulus ratio at the aortic valve took on heightened importance because

of the clinical implications of significant aortic regurgitation. Additionally, retrograde catheter courses from the femoral artery (e.g., advancing the dilating catheter from the ascending aorta into the left ventricle) increased the risk of vascular entry site injury and consequently imposed greater demand for low-profile equipment.

The first report of successful balloon dilation of an aortic valve appeared in 1984.³² The procedure is now routinely performed with good results in newborns, infants, and older children. Indications include moderate to severe aortic stenosis in the absence of more than moderate aortic regurgitation. Rarely in the older infant or child is there coexisting LV dysfunction, although LV hypertrophy is usually apparent, and with progressive degrees of obstruction and age, arrhythmia may become a more prominent clinical feature. In a large series of 192 procedures, percutaneous aortic valvuloplasty resulted in effective relief of severe aortic stenosis (reduction in peak gradient from 77 to 30 mm Hg).³³ Experience has shown that dilation using a balloon inflated to 80% to 100% of the annular dimension of the valve is effective.³⁴ Most procedures can be performed from the femoral artery, even in neonates. Techniques for antegrade, transvenous aortic valve dilation have been described, although this approach is used infrequently in current practice.^{33,35} Freedom from reintervention has been reported in both surgical and nonsurgical series and is estimated at 50% at 8 years after intervention.^{36,37} Repeated dilation of the aortic valve in the case of predominantly obstructive disease is possible, and gradient reduction of 50% at the second procedure can be expected.^{38,39}

Two large single-center experiences with neonatal aortic valvuloplasty have reviewed this procedure comprehensively, describing acute effects as well as observations of ongoing development of the valve. Infants were referred for the procedure based on prostaglandin dependence and/or LV dysfunction. The procedure was highly effective, with relative reductions in gradient of 54% and 69% as measured during the procedure.^{40,41} In the past, this procedure had a significant rate of associated mortality, but this rate has decreased over the almost 2 decades since the first procedure and is now approximately 4%.⁴¹ After retrograde aortic valvuloplasty, femoral pulse loss is common but can be treated with heparin infusion or thrombolytic therapy with some recovery.

New aortic regurgitation occurs in approximately 15% to 30% of infants after neonatal valvuloplasty.^{34,41} Among infants treated primarily with valvuloplasty, a steady increase in the frequency of significant aortic insufficiency has been noted. In a review of 113 young infants, freedom from moderate or severe aortic regurgitation was 65% at 5 years. In this group, survival free of reintervention was 48% at 5 years, a rate similar to that noted in earlier and more heterogeneous series, with many patients presenting for redilation and 16% proceeding to aortic valve replacement within 5 years. Independent predictors of shorter reintervention-free survival included younger age, higher gradient, and larger balloon-to-annulus ratio.

Often, in the setting of multiple left-sided obstructions, a hypoplastic aortic annulus contributes to obstruction that is not acutely relieved by commissural

modification. Of interest, among infants having catheter aortic valvuloplasty, hypoplastic aortic annuli have been observed to demonstrate catch-up growth of sorts, with normalization of hypoplastic left heart structures, including the aortic annulus and the left ventricle, observed within the first year of life. Whether this is directly related to anatomic effects of balloon stretch on the annulus, or secondary to changes in left heart flow following valve leaflet modification, is unknown.

Mitral Valvuloplasty

Whereas the aim of pulmonary and aortic valvuloplasty is to create tears along fused commissures to effect gradient relief, mitral valve dilation appears to create a tear, typically of the anterior leaflet itself or submitral apparatus, that may allow for increase in overall inflow orifice. The technique, applied to patients with rheumatic mitral valve disease, was first reported by Lock and associates in 1985.⁴² Pressed by poor surgical outcomes in young patients with congenital mitral stenosis, Spevak and colleagues attempted balloon mitral valvuloplasty in nine patients, predominantly infants and toddlers.⁴³ The procedure was successful in seven of nine patients with heterogeneous valve morphologies. Further exploration of this innovative intervention confirmed the feasibility of achieving short-term hemodynamic benefit and symptomatic improvement.⁴⁴ Follow-up over a 2-year period showed only 70% survival at 2 years despite dilation, whereas 55% survival was predicted among similar patients undergoing surgery. Indications for mitral valve dilation typically include left atrial and right ventricular hypertension; growth failure is commonly seen in these patients. Attempts to manage congenital mitral stenosis via balloon dilation can be expected to reduce the gradient by 30% using contemporary techniques, with the induction of significant mitral regurgitation in 28% of patients.⁴⁵ Survival at 5 years after surgery has improved from 69% in the early experience to 87% more recently. Even as surgical approaches to valve repair and even pediatric replacement continue to improve, mitral valve dilation will likely continue to play a role in the management of these difficult patients, many of whom will undergo multiple operations over a lifetime.

Pulmonary Valve Replacement

Management of valvular disease in the catheterization lab has been defined for more than 30 years by balloon dilation to relieve obstruction; transcatheter interventions to manage valvar regurgitation did not exist. Only within the past 5 years has the potential to restore valve competency percutaneously become a clinical reality. Among the growing population of older pediatric and adult patients with prior RV outflow tract reconstruction, chronic pulmonary insufficiency is associated with deleterious effects on clinical status and cardiac function.^{46,47} Increased attention to this phenomenon over the past decade spurred changes in clinical practice, favoring semi-elective pulmonary valve replacement in older pediatric patients with RV dilation or dysfunction. This trend in clinical practice coincided with the development of a

FIGURE 107-4 ■ Right ventricular outflow tract angiography in a lateral projection. The highly obstructed and calcified conduit is seen in an immediate retrosternal position. **A**, Contrast injection in the distal conduit demonstrates antegrade flow along the wire course into the right pulmonary artery, as well as severe pulmonary regurgitation opacifying the right ventricle. **B**, After placement of a stent-mounted bovine jugular valve, the pulmonary regurgitation is abolished.

stent-based valve and percutaneous delivery system and provided a candidate population in which to advance the concept of percutaneous valve replacement. A unique convergence of conditions—(1) driving clinical interest, (2) broad interventional experience with stent delivery in RV to pulmonary artery conduits, (3) surgical experience with bioprosthetic valve materials, and (4) multiple precedents for industry collaboration in device development—allowed the process to move rapidly.

The approval of the Melody stent-based, bovine jugular vein valve in 2010 marked a major milestone in interventional catheterization, with subsequent widespread use of this device and dissemination of the procedure.⁴⁸ Although the device was approved for use in patients with dysfunctional RV to pulmonary artery conduits, patients with native outflow tracts and sufficient narrowing to seat the device have now also been treated.⁴⁹ These patients are the target population of newer devices currently under study, tailored to the highly variable anatomy of the postoperative native outflow tract. The original device, used when indicated for conduit failure, effectively relieves obstruction and decreases pulmonary regurgitation as observed angiographically, echocardiographically, and by MRI-derived pulmonary regurgitant fraction (Fig. 107-4).⁵⁰⁻⁵² These improvements are sustained in medium-term follow-up. Perhaps of greatest significance is a demonstrable improvement in New York Heart Association class and measured exercise parameters.⁵³ Early concerns about valve failure related to stent fracture have been addressed in part by changes in delivery technique (pre-stenting), although debate continues regarding the possibility of predisposition of the device to infection.^{54,55} The concept of repeated re-replacement with serial, nested, stent-based devices offers, in theory, the potential for lifetime avoidance of reoperation. It seems likely that many patients will be managed with initial placement of a surgical bioprosthetic valve with subsequent catheter-based interventions. The off-label use of the Melody for valve replacement in other positions, including aortic and mitral, has been described.⁵⁶

Vascular Interventions

All manner of congenital and postoperative vascular obstructions, both venous and arterial, are responsive to balloon angioplasty. Although indications and results vary, the principles of effective angioplasty are common, regardless of the target site. Effective angioplasty is achieved by creating a controlled tear in the vessel wall—ideally, a partial-thickness medial tear. The conditions under which this tear can be produced depend on the intrinsic compliance of the vessel wall and the severity of the obstruction. Mild stenoses and highly compliant lesions are particularly difficult to dilate effectively but may respond to endovascular stent placement. In contrast, severe noncompliant obstructions present significant risk for an uncontrolled transmural tear. To perform angioplasty safely, empiric guidelines around technical variables have been established based on the nature of the vessel being intervened on. Common indications for balloon angioplasty in the treatment of congenital heart disease are coarctation of the aorta and pulmonary arterial stenosis.

Coarctation of the Aorta

Restenosis occurs after surgical repair of coarctation of the aorta, and its incidence has been estimated at 10% to 20%, related to age at repair, and the degree of associated arch hypoplasia.⁵⁷ After pioneering work by Sos and colleagues⁵⁸ and Lock and coworkers⁵⁹ to test the feasibility of balloon dilation on postmortem or surgically excised specimens, Singer and colleagues⁶⁰ reported the first successful balloon dilation of recoarctation in a patient in 1982. Kan and coworkers⁶¹ described the first seven patients in 1983, and, in 1990, the VACA Registry results showed gradient reduction to less than 20 mm Hg in 78% of patients treated.⁶² In 1991, Hijazi and coworkers argued that balloon dilation should be the treatment of choice for recurrent coarctation, based on an 88% success rate and a low rate of complications.⁶³ The field has

generally concurred, and recurrent coarctation is now largely managed in the catheterization laboratory.⁶⁴

Native coarctation of the aorta was one early target for catheter intervention, although the observation of aneurysm formation tempered initial enthusiasm. Through the current era, the reported efficacy of balloon dilation for native coarctation has failed to support primary, non-surgical intervention. Among infants younger than 3 months, authors have described favorable results of balloon dilation of native coarctation³² but with restenosis occurring in more than 50% of patients.^{65,66} Concern over these high restenosis rates and a 5% to 15% rate of late aneurysms has precluded widespread acceptance of angioplasty as primary therapy in unoperated infants.⁶⁷ Therefore, in these younger patients, balloon dilation is pursued primarily as a palliative procedure. Rates of iliofemoral arterial complications, which were high during the early experience with this infant population, have become lower as low-profile dilating balloon catheters have evolved.⁶⁸ In rarer, late-presenting older children and adults with unoperated coarctation, primary catheter intervention can be effective and may be considered an alternative to surgery, although there are few data to support this as a superior approach.⁶⁹ Patients with mild obstruction and potentially poorly developed collaterals may be good candidates for therapy without aortic cross-clamping.

Although the earliest discussion of stent implantation in coarctation described the treatment of severe aortic obstruction, the procedure has proven uniquely effective in treating disease at the other end of the spectrum—mild native or recurrent obstruction.⁷⁰ In this setting (peak gradient < 20 mm Hg), standard balloon angioplasty may be ineffective in the setting of a highly compliant lesion or segmental obstruction. Stent placement can allow a controlled enlargement of a mildly narrowed aorta over the length of the stent.⁷¹ Reduction of even relatively low gradients has been associated with improvement in LV end-diastolic pressure.⁷² Freedom from reintervention after stent placement for coarctation is 50% at 5 years, notably higher than in surgical series, reflecting a deliberate staged approach to transcatheter relief of some obstructions. This high rate of reintervention also reflects aggressive treatment of even mild obstruction, with 40% of reinterventions performed in patients with a gradient of 10 mm Hg or less. Overall, pathologic aortic mural injuries such as aneurysm, dissection, or rupture occurred at the time of dilation or stenting in 3 of 153 patients (2%).⁷³ These potentially catastrophic situations can be managed with placement of a covered stent, and this device is now available in trial. Whether covered stents will prove to be safe as a primary therapy for coarctation or should only be reserved for higher risk situations or as rescue therapy remains to be seen.

Pulmonary Artery Stenosis

As with coarctation, proximal pulmonary arterial obstructions confined to the prehilum area can often be relieved surgically, and balloon angioplasty provides an alternative to an open approach. In contrast, more distal obstructions, often inaccessible to the surgeons, are quite amenable to transcatheter therapy. These obstructions can

occur in association with congenital heart disease, most commonly tetralogy of Fallot variants, or in association with arteriopathies such as Williams syndrome.⁷⁴ Although a poorly studied population before now, older patients with chronic thromboembolic disease may also benefit from transcatheter therapy for relief of distal obstructions.^{75,76}

Tools for pulmonary artery dilations have improved considerably over the recent decade. Initial reports used compliant, low-pressure balloons, with perhaps predictably poor results. Since that time, high-pressure balloons, cutting balloons, and now ultra high-pressure balloons have become staples in labs treating these lesions.

Indications for balloon dilation or stenting of pulmonary arteries include elevated RV pressure, diminished distal flow, or hypertension in unaffected segments as a result of flow maldistribution. Postoperative anastomotic lesions, typically of the proximal branch pulmonary arteries, generally respond well to standard balloon dilation, as do some congenital stenoses and hypoplasia. In contrast, pulmonary arterial obstruction resulting from vessel kinking or compression often requires stent placement to achieve relief.

Using low-pressure balloons, with highly variable relative dilating diameters, the earliest pulmonary artery dilations achieved success in only 38% to 59% of cases.^{58-60,77-79} Results improved as high-pressure balloons came into use; these provided relief of obstruction in up to 72% of vessels.⁸⁰ Despite the use of high-pressure balloons, a significant proportion of pulmonary arterial obstructions remained resistant to balloon angioplasty. Newer strategies to treat these lesions involve cutting balloons that are used to initiate controlled vascular injury at the site of resistant lesions.⁸¹ By using coronary cutting balloons on small-vessel pulmonary arterial lesions resistant to high-pressure angioplasty, operators have substantially increased lumen diameter in 92% of previously refractory vessels.⁸² After the introduction of larger, peripheral cutting balloons, this technology has been applied to larger-caliber vessels with good effect, although the percentage increase in lumen diameter was less dramatic in these larger vessels.⁸³ The most recent addition to the treatment of pulmonary artery stenosis is the ultra high-pressure balloon, developed to treat peripheral vessels or grafts in adults. These balloons, capable of achieving inflation pressure of 30 atm (relative to 4 to 8 atm of a conventional balloon) can be applied to treat highly resistant lesions, whether native vascular obstruction or previously placed stents in noncompliant segments.⁸⁴

Balloon angioplasty of pulmonary vessels is associated with an appreciable rate of complications, some of which can be life-threatening. When obstruction to highly stenotic vessels is relieved, distal vessels may be exposed acutely to higher pressure, resulting in pulmonary edema.⁸⁵ This consequence can usually be averted by limiting relief of obstruction to create mean distal pressures not in excess of 25 mm Hg. Direct trauma to the dilation site can create obstructive intimal flaps, contained tears, and vascular rupture.⁸⁶ Strategies to manage these complications should be directed at reestablishing an unobstructed lumen (in the case of a flap), maintaining

FIGURE 107-5 ■ Early postoperative pulmonary angiography in an infant after a bidirectional Glenn operation. Flow from the superior vena cava travels exclusively into the right pulmonary artery. **A**, A “beak” is evident at the site of acquired left pulmonary artery atresia. **B**, After wire recanalization and stent placement, bilateral pulmonary flow is reestablished.

distal flow, and controlling any hemorrhage. In some cases, uncontrolled tears may be managed by temporary occlusion of upstream vessels, when this maneuver can be hemodynamically tolerated. Occasionally, feeding vessel occlusion, using a coil or other occlusion device, may be necessary.

Balloon-expandable stents have been used successfully to relieve pulmonary arterial obstruction since the early 1980s. Stents were first applied predominantly in proximal branch pulmonary artery stenoses in larger children, simply because of the size of the available stents, the size of the stent or balloon delivery system, and the risk of iatrogenic “restenosis” caused by the stent after somatic growth. After experimental evidence that endovascular stents could be safely and effectively redilated, McMahon and associates reported on mechanisms of successful redilation in a large group of patients.⁸⁷ The introduction of more flexible, smaller, and lower-profile stenting systems in the early 2000s resulted in stents being placed more frequently in distal vessels and in infants and smaller children.^{88,89} Using tools such as ultra high-pressure balloons, the potential for some degree of further stent expansion at a later date can be presumed. In the case of early postoperative anastomotic obstruction, stent placement may be preferable to simple angioplasty, because vessel occlusions or stenoses can be opened without using oversize balloons and risking vessel or suture line rupture (Fig. 107-5).⁹⁰

Conduits, Systemic and Pulmonary Veins

Transcatheter angioplasty techniques have also proved valuable in extending the life of allograft or prosthetic shunts in palliated postoperative patients, such as those with RV to pulmonary artery conduits after stage I for HLHS or those with conduits used in RV outflow tract reconstruction as in tetralogy of Fallot with pulmonary atresia. These grafts can become obstructive and require replacement because of contraction, kinking, neointimal “peel” accumulation, external compression, or simply patient growth. Standard balloon angioplasty

rarely provides definitive relief, although ultra high-pressure balloons have been used with greater success.⁹¹ Predictably, balloon expandable stent placement can effectively delay the need for surgical reintervention although at the expense of loss of competency of any existent valve.^{92,93} In a single-center review of 221 patients with stents implanted in RV to pulmonary artery conduits, acute hemodynamic changes after stenting included significantly decreased RV systolic pressure and peak RV to pulmonary artery gradient. Stents could be redilated, and at subsequent catheterization, additional stents could be placed. By Kaplan-Meier analysis, median freedom from conduit surgery after stenting was almost 3 years. Younger age, smaller conduit diameter, and higher ratio of RV to aortic pressure predicted shorter freedom from surgery.⁹⁴

Systemic venous obstruction occurs in a number of postoperative congenital cardiac settings, most notably in patients after atrial switch procedures. In both cardiac and noncardiac patient populations, systemic venous obstruction occurs with increasing frequency as a result of chronic indwelling catheters and, in some cases, cannulation for extracorporeal membrane oxygenation. Both angioplasty and stent placement have been applied successfully in the setting of superior vena cava obstruction.^{95,96} Patients with extensive venous obstruction have been treated for the classical symptoms of superior vena caval syndrome but also for some less well understood indications, including respiratory insufficiency.⁹⁷ In these cases, elevated superior caval pressure is thought to contribute to impairments of pulmonary lymphatic drainage and thus lung function. The superiority of stent placement over simple balloon angioplasty with regard to gradient relief and durability of result is suspected but has not been firmly established, although stent placement should be carefully considered in the young infant with anticipation of significant superior vena cava growth over a lifetime.

Pulmonary vein stenosis that occurs either as “isolated” disease or in the context of congenital heart disease, particularly in young infants, remains one of the most challenging lesions to treat, either by surgery or with

transcatheter techniques. On the basis of favorable results after balloon dilation angioplasty of congenital lesions, Driscoll and colleagues attempted pulmonary vein dilation in the early 1980s, and they observed early restenosis associated with clinical decline.⁹⁸ Endovascular stents applied to pulmonary venous obstruction almost a decade later failed to alter the course of the progressive and intractable reobstruction, which rapidly redeveloped within months of intervention.^{99,100} All manner of therapies have been attempted in limited settings, including mass removal/endovascular biopsy, covered stents, drug-eluting stents, and rotational atherectomy. None of these have provided any measurable advantage in the treatment of pulmonary vein stenosis. Currently, we use standard high-pressure and cutting balloons rather than more elaborate tools, reserving stenting for multiply reobstructed vessels or those with clear kinking at the left atrial junction.^{101,102} None of these therapies has consistently provided lasting relief of obstruction/favorable remodeling; thus, frequent reintervention is often necessary, sometimes as often as every 8 to 10 weeks.

Defect Occlusion

To date, transcatheter relief of obstructions, whether valvar or vascular, has been accomplished largely by applying relatively simple devices, such as angioplasty balloons or balloon-expandable stents. In contrast, the field of defect closure has been defined by the variety of devices developed. In 1987, after almost 20 years of development, Rashkind and colleagues described the use of an occluding device to treat patent ductus arteriosus (PDA).¹⁰³ Since that time, numerous catheter-based devices have been used to close defects without surgery. These devices have encompassed a range of sizes, configurations, materials, delivery systems, and release mechanisms. They not only have been implanted in patients with PDA, ASD, and ventricular septal defect (VSD) but also have been used for innovative indications, including such lesions as perivalvular leak, coronary artery fistula, and pulmonary arteriovenous malformation.^{104,105}

Despite the broad range of devices produced and evaluated, only a few have been fully approved and marketed for use in patients with congenital heart disease. Perhaps the greatest evolution in the fields of pediatric interventional cardiology and device closure has been the engagement of the regulatory process by the interventional community. Only by carefully designing and carrying out intelligent, nonrandomized, multicenter trials has there been sufficient enrollment of patients and data collection to support device approval applications. Even so, the number of patients enrolled and devices implanted is typically in the range of a few hundred, and follow-up periods are relatively short. Ongoing evaluation of each approved device is the responsibility of the implanting interventional cardiology community.

Patent Ductus Arteriosus, Collaterals, and Shunts

The development and ultimate U.S. Food and Drug Administration (FDA) approval of the Amplatzer duct

occluder device changed the entire approach to PDA. The history of attempts at device closure of PDA provides a useful introduction to general principles of transcatheter defect closure. In 1967, Porstmann and colleagues reported the use of foam plugs to occlude PDA via a transcatheter approach.¹⁰⁶ After this isolated experience, a full decade elapsed before the Rashkind PDA occluder was developed to close moderate-size PDAs. Although more effective than the previous device, a high incidence of incomplete closure made it a poor alternative to surgical closure, and it never came to market.^{103,107} Ultimately, PDAs were effectively closed by catheter delivery of the Gianturco vascular occlusion coil used in an off-label fashion. This conceptually simple, inexpensive, versatile, and easy-to-use device rapidly came into widespread use. Coil occlusion of small PDAs (<3 mm) became a routine catheter procedure. Most small PDAs could be safely and effectively closed using a single coil,^{108,109} and closure rates when multiple coils were available were 93%.^{110,111}

Closure of larger PDAs continued to prove a challenge, often requiring multiple coils or advanced coil delivery techniques, with attendant increase in rates of embolization and residual flow. One device, essentially a sac designed to retain a large coil cluster, was approved for vascular occlusion, but the combination of a large delivery system, expense, and a complex delivery mechanism were unacceptable to most implanters.¹¹² The unsatisfactory results of coil-based approaches to large PDAs spurred a search for a different type of device, and the plugging concept was reexplored. In 1998, the Amplatzer duct occluder device received approval after a multicenter trial demonstrated successful closure of larger PDAs (>3.5 mm), with closure rates of 100% at the 1-year follow-up. The advantages over the existing products included ease of use, low-profile delivery, and retrievability.¹¹³ The recently approved Nit-Occlud device, resurrecting the coil concept, further increases the likelihood that the isolated PDA in an older infant or child will rarely be encountered by the cardiac surgeon.¹¹⁴ Although the hemodynamically important PDA in the premature infant has also been treated using these devices, in this population, surgical intervention remains the standard.¹¹⁵

In the setting of more complex heart disease, devices such as embolization coils and vascular occluders can be used to advantage in management of unwanted extracardiac shunts, whether biologic or prosthetic, as well as in the management of intracardiac defects. Aortopulmonary collateral vessels, commonly seen in patients with palliated single ventricle disease, may impair postoperative recovery by imposing a disadvantageous volume load on the single ventricle. Furthermore, they can inhibit efficient oxygenation by competing with caval flow for entry to the peripheral pulmonary vasculature, and they may contribute to persistent pleural effusions postoperatively.¹¹⁶ Closure of these vessels to decrease unwanted return into the field at the time of operation remains controversial, as flow studies have questioned the extent of their contribution to pulmonary venous return. Recent MRI data suggest that prior reports may have underestimated the flow capacity and clinical consequences of these vessels. Using embolization coils or particles,

flow may be eliminated in up to 75% of treated aortopulmonary collaterals in patients with congenital heart disease.^{117,118}

Occlusion devices may also be used in occlusion of iatrogenic shunts, such as a supplementary Blalock-Taussig shunt or a stented PDA in a patient with pulmonary atresia with an intact ventricular septum (PA/IVS). In patients with pulmonary atresia who undergo RV decompression, the shunt may become superfluous as RV compliance improves. At subsequent hemodynamic assessment, if shunt occlusion is indicated, it can be performed with high rates of total occlusion and minimal risk for adverse events, sparing the patient reoperation.¹¹⁷

Atrial Septal Defect Closure

Since the first clinical report of percutaneous, device-based ASD closure by King and Mills in 1974, transcatheter closure has repeatedly been shown to be feasible, safe, and effective in both standard-risk and high-risk surgical patients.¹¹⁹ This procedure is now available in most centers as an alternative to surgical closure for typical ASDs, although surgical closure may still yield the best outcome in specific cases. All catheter-based procedures for ASD closure rely on the implantation of a device that has some overlap onto surrounding septal tissue to permit device stabilization. These devices are appropriate only in secundum defects and have never been credibly applied to sinus venosus or primum-type ASDs. Furthermore, not all secundum ASDs are candidates for device closure, depending on their size and proximity to other cardiac structures (e.g., the aortic root, superior vena cava, or atrioventricular valves). Variability in septal defect size, shape, and position has thwarted efforts to design a single device that could be uniformly successful in closing ASDs (Fig. 107-6). As a result, a myriad of devices have been used, but results are difficult to compare because of inherent differences in mechanisms and timing of closure. Each device also results in unique unintended outcomes, including failure to implant, device fracture, erosion, malposition, and late embolization.

Early devices were based on the double umbrella concept, and in 1989, the clamshell device was the first to be implanted under protocol of a prospective multicenter investigational device exemption (IDE) trial. Although results were promising, difficulties with the device and the process of approval resulted in the abandonment of this device in favor of a second generation of umbrella devices. An alternative approach was pursued with the Amplatzer atrial septal occluder, which incorporated self-centering capability and retrievability into a remarkably simple and effective design. In 2002, the Amplatzer atrial septal occluder became the first device to receive FDA approval based on reports of a 100% successful implantation rate, a complete closure rate of 98%, and a low rate (2%) of complications.¹²⁰ This device was designed to close secundum ASDs up to 38 mm in diameter. Comparison with surgical closure showed comparable rates of defect closure (99%) and adverse events (8%). However, device closure offered the benefit of

shorter length of stay and lower rate of major adverse events. Subsequently, a second device was approved for closure of smaller ASDs. In a multicenter trial, the Helex device (Gore and Associates, Flagstaff, AZ) was implanted in 143 patients who had an ASD less than 22 mm in diameter, with good results.¹²¹ Closure rates using this device were comparable to surgery, although the size of the candidate defect was a limitation, and a 25% incidence of small residual leak was recognized. This device received approval in 2006, at which time development of an alternatively configured device with a somewhat simplified delivery system was already under way. The Gore Septal Occluder, marketed overseas, has yet to receive approval and is still in trial in the United States.

Ongoing evaluations of these devices have revealed late device-related complications, including malposition/embolization, thrombus formation, and erosion.^{122,123} When embolization occurs, devices can often be retrieved using tools such as intravascular snares. The potential for entrapment of the device, or valvar damage, should be considered and may dictate that surgical removal is a safer solution. The incidence of thrombus formation appears to be related to device type, although whether delivery, materials, or device configuration plays a causative role remains unknown.¹²⁴ Erosion has been reported immediately after implantation, as well as several years later, and can be catastrophic. Its occurrence remains rare but disturbingly poorly predicted. It is believed to result from ongoing radial and possibly rotational forces exerted by the edge of the device on cardiac tissues.¹²⁵ Biodegradable closure devices have historically been a topic of great interest, based on the potential superiority with regard to profile and thrombogenicity. These devices have thus far failed to equal the performance of the currently available, more traditional occluders.

Although most small or moderate-sized secundum ASDs can be closed using intracardiac devices, surgery remains the primary approach for most types of VSDs requiring closure. Some exceptions exist, as in the case of very apical or anterior muscular defects, postoperative intramural defects, or extensive multiple muscular defects (i.e., the “Swiss cheese” septum).^{126,127} These VSDs pose significant surgical challenges and may ultimately be most effectively managed through a combination of surgical and catheter intervention, or hybrid approach.

Ventricular Septal Defect Closure

The earliest attempts at transcatheter closure of VSDs, using a double umbrella device, were described by Lock and colleagues in 1988.¹²⁸ These authors described technical aspects and feasibility of the procedure for six patients who were not considered candidates for operative closure. Bridges and coworkers¹²⁹ added to the experience with a review of highly selected patients with muscular VSD occurring in association with complex heart lesions who underwent device closure. It was suggested that preoperative transcatheter closure could simplify subsequent surgical repair of relatively inaccessible lesions.¹²⁹ In the first large reported experience with transcatheter VSD closure, patients considered high risk for surgical VSD closure were treated with transcatheter

FIGURE 107-6 ■ Lateral projection images during transcatheter atrial septal defect closure with fluoroscopic and transesophageal echocardiographic imaging. **A**, Balloon sizing of a small defect. **B**, Imaging during partial deployment of the right atrial disc after complete formation of the left atrial disc, using a Helex device. **C**, Balloon sizing of a larger defect with minimal waist apparent on anterior aspect of balloon. **D**, Following left and right atrial disc deployment of an Amplatzer septal occluder, right atrial angiography aids in confirming appropriate position, particularly inferiorly.

device and showed improvement on a composite VSD size and severity scale.¹²⁷ However, the complex catheter courses, the size of the delivery system, and the vulnerable hemodynamic situation of patients resulted in a high rate of major adverse events, perhaps 45%.

Results of muscular VSD closure using the Amplatzer muscular VSD device were reported in 2004.¹³⁰ This device, similar in concept to the Amplatzer duct occluder and the Amplatzer septal occluder devices, offered the advantage of a smaller delivery system and a significantly

lower adverse event rate (11%) when compared with results for prior VSD devices. The procedural success rate of only 86% reflects the fact that despite significant improvements in deliverability of devices, transcatheter VSD closure remains a technically challenging intervention. Among 75 patients treated with the Amplatzer muscular VSD device, late complete closure was achieved by echocardiographic criteria in 92%, although follow-up was incomplete. This device received FDA approval for marketing in 2004. Periventricular delivery, or even

intraoperative delivery under direct visualization, has been described and should be considered as part of a surgical strategy for closure of complex, multiple muscular defects.

At this time, the feasibility of device closure of perimembranous VSD using an asymmetric device has been demonstrated and there is growing clinical experience overseas.¹³¹ However, no membranous VSD device has yet received domestic approval. The risks of percutaneous device delivery include interference with aortic and atrioventricular valves, leading to regurgitation, and device-related conduction abnormalities, including heart block. In the context of widely available surgical therapies with excellent results, outcomes of transcatheter closure will likely have to be improved over those seen thus far to justify a primarily device-based treatment.

COMPLICATIONS

In large centers, between 55% and 75% of all catheterizations now involve intervention.¹³² As with all minimally invasive techniques, effective transcatheter interventions for congenital heart disease offer the potential for treatment with lower morbidity and cost. However, the indirect nature of these catheter procedures also creates a unique set of potential complications. The overall rate of serious complications from interventional catheterization, investigated repeatedly, ranges from 3% to 7%.¹³³⁻¹³⁵ Although relatively few of these complications (approximately 2%) require emergent surgery, interventional procedures should not be undertaken unless surgical backup is available. Complications requiring surgical intervention include access vessel injury, valvar disruption, cardiac perforation, and device malposition or embolization.¹³⁶ A collaborative relationship between the interventional cardiologist and the pediatric cardiac surgeon allows each to better understand the benefits and risks of the two different therapeutic modalities.

SURGICAL COLLABORATION

Although hybrid procedures, using combined surgical and catheter collaboration, have been performed for decades, the publication of results of the hybrid stage I procedure for HLHS launched an era of enthusiastic expansion of this type of approach.^{137,138} The hybrid stage I was initially described as open chest placement of pulmonary artery bands, with direct main pulmonary artery access for placement of a catheter-delivered stent in the PDA and, often at a later procedure, the creation of an unrestricted ASD. Results at selected centers that gained routine experience with this approach were as good as standard surgical stage I, and because the patients were spared cardiopulmonary bypass and circulatory arrest, postprocedural recovery was remarkably rapid. At this time, most large centers continue to routinely perform surgical stage I.

The rewards of more extensive interventionalist-surgeon collaboration and promotion of the broader hybrid concept remain compelling. These approaches

will no doubt be applied more widely as devices for management of ASD, VSD, and valve failure become more sophisticated and widely available. Surgical control will allow the delivery of intravascular devices to be independent of access vessel patency or size and will also allow for stabilization of nonsecured devices. Balloons and stents, developed for percutaneous use, will increasingly become part of the surgeon's toolbox with procedures such as intraoperative stent placement or combined valve commissurotomy with annular balloon expansion. As experience with these collaborations accrues, the cross-disciplinary knowledge gained will benefit the field.

Surgeons and interventional cardiologists will also collaborate in the management of the postoperative patient. As patients with increasingly complex anatomy present for repair and can be supported with ever-improving intensive care, the opportunity to perform postoperative invasive assessment will present more frequently. Early intervention on residual postoperative lesions can be carried out safely and may shorten stays or reduce residual hemodynamic burden prolonging hospitalization.^{139,140} A generally held belief that angioplasty is safer after approximately 6 weeks following surgery will likely never be proven, and, to the contrary, increasing experience with intervention on postoperative obstruction will likely prove useful in postoperative management.

As extracorporeal support and circulatory assist devices are applied to greater numbers of patients with congenital heart disease, new situations will present themselves to the interventionalist. In cases of extracorporeal membrane oxygenation support, left atrial decompression may be necessary to protect from excessive pulmonary venous hypertension and pulmonary hemorrhage. This procedure can be performed safely and can be associated with near immediate improvement in pulmonary conditions of the circulation at various levels of device support.¹⁴¹

FETAL INTERVENTION

Background

The rationale for fetal cardiac intervention, as for all fetal invasive procedures, is based on the premise that intervention in the rapidly changing and potentially highly responsive fetal environment may alter the natural history of a developmental error and possibly avert serious, even lethal, postnatal disease. For intervention to be considered, the diagnosis must be certain, the procedure must be feasible, and the risk of fetal or neonatal morbidity without intervention must be sufficient to justify the risk posed to both fetus and mother. Given the rapid sequencing of serial heart development, once developmental derangement is diagnosed, early intervention likely yields the greatest potential for significant clinical benefit.

Fetal Cardiac Interventions

Conditions for which prenatal cardiac interventions may be considered include those in which (1) the fetus is at risk for demise as a result of the condition, (2) the

TABLE 107-1 Congenital Cardiovascular Anomalies Potentially Amenable to Prenatal Intervention

Indication for Intervention	Condition	Intervention
Risk of fetal death	Congenital heart block	Pacemaker
	Severe congenital MR with AS and intact atrial septum	Maternal pharmacotherapy Balloon aortic valvuloplasty
Risk of acute neonatal instability or death	HLHS with intact atrial septum	Creation of ASD
	Obstructed, totally anomalous pulmonary venous return	Creation of ASD Stenting of obstructed vertical vein or ductus venosus
Risk of primary anomaly evolving into more severe condition	Fetal AS with evolving HLHS	Balloon aortic valvuloplasty
	Pulmonary atresia with evolving HRHS	Pulmonary valve perforation and dilation
	Premature closure of ductus arteriosus	Ductal stenting
	Absent pulmonary valve syndrome	Closure of pulmonary valve

AS, Aortic stenosis; ASD, atrial septal defect; HLHS, hypoplastic left heart syndrome; HRHS, hypoplastic right heart syndrome; MR, mitral regurgitation.

disorder is likely to result in acute neonatal instability or death, or (3) intervention may alter the evolution of the disease so that the postnatal morbidity is substantially reduced. Potential examples of these classes of indication are listed in Table 107-1. Of course, the ability to carry out an appropriate intervention must be taken into consideration. To illustrate this point, although fetal Ebstein anomaly and severe fetal mitral regurgitation pose risks of hydropic demise, fetal interventions to address atrioventricular disease do not exist. In contrast, fetuses with HLHS face a significant risk of neonatal mortality and lifelong morbidity, and in the cases related to aortic stenosis, a procedure can be performed to dilate the aortic valve. The clinical benefit of the procedure depends on the probability that the anatomic change imposed by the successful intervention in utero will alter the subsequent course of cardiac growth and development sufficiently to have a major impact on survival or postnatal outcome.

The mechanism through which anatomic modification of the fetal heart alters subsequent development is postulated to be through alteration in loading conditions. Although there is no conclusive evidence that abnormalities or alterations of flow or loading contribute to the development of cardiovascular malformations in the human fetus, data from various experimental animal systems support this contention. Fetal lambs exposed to chronically decreased LV preload by late partial occlusion of the left atrial cavity exhibit significant decrease in combined ventricular output and placental blood flow and a significant decrease in LV mass and volume.¹⁴² These changes appear to be time dependent, with more marked alterations in fetuses with longer exposure to decreased LV inflow. In another model, in fetal lambs exposed to increased LV afterload by banding of the ascending aorta, there is a decrease in combined ventricular output, in conjunction with a significant decrease in LV chamber volume and an increase in LV wall thickness.¹⁴² Initially, LV weight increases relative to the weight of the RV, but with a prolonged duration of aortic banding, the ratio of LV to RV weight decreases significantly. These studies and others demonstrate that alterations in ventricular loading or embryonic blood flow patterns in normal fetuses and embryos can be associated with cardiovascular development and function.

The potential for prenatal cardiac intervention has been realized for nearly three decades; as early as 1986 there was a reported attempt at in utero pacing for fetal complete heart block.¹⁴³ By 1991, there were reports of prenatal aortic valve dilation and prenatal pericardiocentesis in human fetuses.^{144,145} Through the 1990s, there were several additional reports of human fetal cardiac intervention, mostly sporadic, primarily for aortic stenosis.¹⁴⁶ Also during this period, a number of animal studies were performed to investigate the pathophysiology of cardiac bypass and cardioprotection in the fetus, anticipating fetal cardiac surgery, as well as alternative approaches to transvascular fetal cardiac intervention.¹⁴⁷⁻¹⁵⁰

In 2000, we at Boston Children's Hospital initiated a program for fetal cardiac intervention, focusing on treatment of fetal aortic stenosis with evolving HLHS. Later, the program expanded to include procedures for established HLHS with an intact or highly restrictive atrial septum, pulmonary atresia with evolving hypoplastic right heart syndrome, and structural anomalies causing fetal hydrops.¹⁵¹⁻¹⁵⁶ At this time, more than 160 procedures have been carried out, numerous publications have described our experience, and the outcomes of the first 100 procedures for fetal aortic stenosis have recently been reported.¹⁵⁷

General Approach to Fetal Cardiac Intervention

Common to all of the procedures that we perform is a percutaneous ultrasound-guided approach with maternal and fetal anesthesia. In an operating room environment, with the mother supine with left lateral tilt for uterine displacement, the location of the placenta and the fetal orientation are determined using conventional ultrasonographic techniques. A combination of spontaneous fetal movements and external version maneuvers are used to accomplish fetal positioning, and once an approach vector for percutaneous cardiac puncture is identified, fetal intramuscular anesthetic is administered intramuscularly. In the early experience, a limited laparotomy without externalization of the uterus was used to enable direct, manual, transuterine fetal positioning. This incision has been largely obviated by the application of more refined

FIGURE 107-7 ■ Fetal echocardiography during prenatal intervention for critical stenosis of the fetus with evolving hypoplastic left heart syndrome. The left ventricle is dilated and dysfunctional, appearing globular, and the stainless steel needle is positioned to enter the ventricle from the apex.

maternal/fetal selection criteria and improvements in the techniques of cannula manipulation. Access to the target is achieved by direct puncture of the maternal abdomen, uterus, fetal chest wall, and the target cardiac chamber. The most commonly used cannula is a 19-gauge, 11-cm-long biopsy needle with a sharp, solid stylet and a non-beveled, dull edge, because this instrument is commercially available (Fig. 107-7). The length enables percutaneous access in most mothers between 20 and 30 weeks gestation and with a body mass index of less than 40. The inner and outer diameters of this thin-walled cannula allow for passage of most coronary artery angioplasty balloons while minimizing the potential for uterine/placental trauma and pericardial effusion.

Aortic Stenosis with Evolving HLHS

A subset of patients born with HLHS are diagnosed during the mid-second trimester with valvar aortic stenosis and a left ventricle that is normal in size or dilated but has severe dysfunction. When the left ventricle is normal in size or dilated, abnormal physiologic features associated with progression to a diagnosis of HLHS at birth include retrograde flow in the transverse aortic arch, truncated, monophasic mitral valve inflow, and left-to-right flow across the foramen ovale.¹⁵⁸ We refer to such mid-gestation fetuses as having severe aortic stenosis with evolving HLHS. The goal of fetal aortic valve dilation is to avert HLHS in favor of a biventricular postnatal circulation.

Predicting the evolution from aortic stenosis with a normal-size or dilated left ventricle in mid gestation to HLHS at term is complicated, and although several predictive models have attempted to predict left heart adequacy among neonates with aortic stenosis,¹⁵⁹⁻¹⁶¹ choosing the optimal approach in a given patient remains a challenge. Furthermore, few prenatal studies report serial data, and most include only a small number of fetuses.^{162,163} Nonetheless, mid-gestation fetal aortic stenosis that does not progress to HLHS is rare, and it can be distinguished from aortic stenosis with evolving HLHS on the basis of the previously described physiologic features.¹⁵⁸

Decreasing LV afterload and promoting flow through the left side of the heart by relieving aortic obstruction may help prevent progressive left heart dysfunction and growth failure over the subsequent course of gestation. Candidates with the diagnosis of aortic stenosis with evolving HLHS should be considered in light of (1) the likelihood that a technically successful procedure can be performed, and (2) the potential for salvage of the left heart—that is, the potential for LV functional recovery and growth enabling a biventricular circulation postnatally.

Fetal aortic valvuloplasty is performed according to the general practices outlined earlier. The goal is to enter the left ventricle apically but away from the interventricular septum, with a trajectory that is in line with the outflow tract. The dilating balloon size, a function of nominal balloon size and inflation pressure, is targeted to a balloon-to-annulus diameter ratio of 1.0 to 1.2. Once the cannula has been advanced to the LV cavity and the stylet removed, the coaxial guidewire and dilating balloon are introduced down its lumen, and the wire is used to probe for the orifice of the aortic valve. Once the wire is clearly visualized in the ascending aorta, the balloon is advanced across the valve and serial inflations are performed with an inflation gauge after systematic adjustment of balloon depth. When it is clear that the valve has been dilated, the entire cannula-balloon system is removed from the fetus and mother without resheathing the balloon into the cannula, and ultrasound imaging is continued. Treatment for fetal hemodynamic instability or hemopericardium is administered as necessary.¹⁶⁴

We reported our initial experience with aortic valvuloplasty for fetal aortic stenosis in 2004.¹⁵³ In 2007, we reviewed outcomes of 56 fetuses with similar echocardiographic features at diagnosis, 28 of whom underwent technically successful aortic valve dilation, in an attempt to characterize a number of potentially important physiologic changes that occur after successful fetal aortic valvuloplasty.¹⁶⁵ On follow-up echocardiography at 32.8 ± 2.8 weeks, all control (unintervened) patients continued to have retrograde flow in the transverse aortic arch and exclusively left-to-right flow across the foramen ovale; notably, left heart structures seemed to become frozen in their anatomic size once we made the diagnosis of critical aortic stenosis with impending HLHS, and thus they became progressively more abnormal as the fetus grew.

Refinement of selection criteria has increased the percentage of infants achieving biventricular outcome after fetal aortic valve dilation, and at this time, almost 50% will not require a stage I procedure. Pediatric follow-up of these infants born after fetal aortic valvuloplasty reveals that many have significant, persistent, and sometimes refractory dysfunction of both left heart valves and myocardium. Many have significant medical and surgical burden through early childhood. With the oldest survivor just now reaching teen years, we look forward to continuing to learn what the longer-term natural history of “averted” HLHS will be. We continue to work to improve our understanding of how best to select fetuses with aortic stenosis and evolving HLHS for prenatal aortic valvuloplasty and when to intervene for optimal benefit.¹⁵⁷

HLHS with Intact or Restrictive Atrial Septum

HLHS with an intact or highly restrictive atrial septum can be diagnosed on the basis of fetal imaging of the septum in conjunction with demonstration of markedly abnormal pulmonary venous flow patterns in dilated-appearing pulmonary veins.¹⁶⁶ Although limited pulmonary venous egress may be well tolerated in utero, neonates with major septal restriction are at substantially higher risk of death than are those without such restriction.^{15,18,167} They present with profound hypoxemia after birth and often shock. Chronic pulmonary venous hypertension in utero also appears to cause pulmonary venous changes, contributing to neonatal and perioperative morbidity and mortality over the course of single ventricle palliation.

Prenatal intervention may be of benefit in fetuses with HLHS and an intact atrial septum with respect to both of the major problems posed by the restriction of pulmonary venous outflow. If the left atrium can be decompressed before birth, the profound hypoxemia and acidosis that can occur shortly after birth may be prevented and the morbidity of these metabolic insults and the risks of emergency neonatal intervention can be avoided. Also, if pulmonary venous decompression can be achieved sufficiently early in gestation, the pulmonary venous remodeling that occurs may be prevented or given an opportunity to subside or reverse. We first reported atrial septoplasty for fetuses with HLHS and intact atrial septum in 2004, and cases of prenatal atrial septoplasty for this condition have been reported by investigators from other centers as well, using various monitoring and interventional approaches.^{152,168}

In theory, immediate treatment of left atrial hypertension on diagnosis would maximize the potential benefits. However, technical difficulties encountered in performing the procedure on very young fetuses have led to a shift in focus. Rather than risk fatal events in very young fetuses for the advantage of long-term preservation of pulmonary vasculature, we have prioritized early neonatal stabilization, which is dependent on a maximal ASD at the time of delivery, therefore favoring intervention later in gestation (i.e., early to mid third trimester).

The atrial septum is typically approached from the right atrial aspect. The atrial septum is perforated with a sharp instrument, either the access cannula or a smaller-gauge ultra-sharp biopsy needle, after which a dilating balloon is used to enlarge the newly created atrial defect. The largest effective balloon that can be introduced through equipment currently in use is less than 4 mm. The size of the resultant defect, as measured by intraprocedural ultrasound, is invariably smaller than the size of the dilating balloon, ranging from 1 to 3 mm. When the atrial septum appears very thick and there is an expectation that simple balloon dilation will result in septal recoil and only a very small communication, septal stent placement is feasible but exceedingly challenging.¹⁵⁶

We recently reported our experience with prenatal intervention for 21 fetuses with HLHS and an intact or highly restrictive atrial septum.¹⁶⁹ Fetal demise occurred in two cases after the intervention, and complications,

including bradycardia and pericardial or pleural effusion, occurred in eight procedures. Among neonates delivered after fetal intervention for HLHS with highly restrictive or intact atrial septum, surgical survival remains poor (58%), although in utero creation of an ASD did appear to have some benefit in terms of pre-stage I management.

Pulmonary Atresia with Intact Septum

Isolated cases of fetal pulmonary valvuloplasty in the third trimester have been reported by several groups.¹⁷⁰⁻¹⁷² It is impossible to determine from isolated cases whether prenatal intervention has the intended benefit. Since 2002, we have offered prenatal pulmonary valvuloplasty for selected mid-gestation fetuses with pulmonary atresia and evolving hypoplastic right heart, with the intent of promoting right heart growth and functional development and increasing the likelihood of a biventricular circulation after birth. Identification of potential candidates for prenatal treatment of PA/IVS has been a challenge, given the rarity of the disease, the wide spectrum of severity, and the paucity of insight about prenatal predictors of biventricular circulation.¹⁷³ Technically, the procedure presents a unique challenge because the RV (as opposed to the left ventricle in fetal aortic stenosis) is usually hypoplastic (rather than dilated) and the angle of the pulmonary valve arising off the conus can be very difficult to achieve. The effects of this strategy on right heart growth and functional development, and, ultimately, on postnatal outcome, remain to be determined.

Much remains to be learned about the benefits and potential adverse effects of prenatal cardiac intervention. Since our first procedure in 2000, referrals have grown steadily, with more than 90% of prospective and actual patients coming from outside our usual geographic catchment area. Ultimately, the value of prenatal cardiac intervention will depend on a variety of clinical and technological factors, including more frequent, earlier diagnosis of congenital heart disease in utero, characterization of prognostic features in fetuses with congenital heart disease, better understanding of the optimal gestational windows and their capacity for cardiovascular remodeling after fetal intervention, and improved and focused technology. Advances in imaging technologies and specially developed instrumentation should facilitate greater precision and effectiveness of intervention and may open the door to procedures for other, more complex indications.

Thoracic incisions traditionally used in adult cardiac and thoracic surgery have been used in children with varying success with respect to exposure, pain, and cosmetic result. Special considerations relevant to pediatric surgery are related to the lack of development and growth of soft tissue structures such as breast tissue and bony structures such as ribs and vertebra. Thus, incisions that fix growing bony structures, such as ribs in a posterior or lateral thoracotomy, may lead to scoliosis.¹ Anterior thoracic incisions may also injure underdeveloped breast tissue and pectoral muscles, resulting in chest wall deformities and sensory loss. Then again, the flexibility of the chest cage and ribs in young children permit the use of limited incisions with adequate exposure of relevant structures, whereas in adults this may not be possible without the

risk of rib or sternal fracture or instability of the chest cage. Therefore, these factors should be considered when selecting the optimal approach to intrathoracic structures in children, to optimize exposure and for the safe conduct of the procedure, and to minimize pain and achieve a cosmetically acceptable result.

The child should be positioned so that the surgeon and assistant have a direct view of the relevant anatomic structures and so that the anesthesiologist has access to the airway and major access lines. Because the head size of newborns and infants is significantly larger in proportion to the chest than it is in older children and adults, a shoulder roll should be used when children are placed supine on the table, to elevate the shoulders and relieve some of the pressure from the occiput. Soft padding, such

as gel-filled plastic bags, should be placed under all pressure areas. Cooling or heating blankets are used routinely in pediatric cardiac surgery, but these require relatively direct patient contact to optimize heat transfer. Perforated blankets, filled with cold or heated air that is blown through, have improved heat-transfer properties compared with water-filled blankets. Direct skin contact should be avoided, however, with either method, because injury to the skin can result in full-thickness skin loss, particularly in infants. For a lateral thoracotomy, an axillary roll is used to elevate the thorax and relieve pressure on the shoulder and potentially the brachial plexus. As with any thoracotomy incision, care must be taken not to extend the arm and shoulder under tension, even in infants, because this may cause injury to the brachial plexus.

For cosmetic purposes, the skin incision can be placed below the actual entry site into the thorax, whether the incision is a sternotomy or a lateral intercostal approach. Care must be taken, however, to minimize creation of flaps, particularly in infants, because this often leads to breakdown of subcutaneous tissue with fat necrosis, resulting in wound separation. Excessive use of cautery, particularly in the subcutaneous fat in infants, is another cause of fat necrosis and wound separation, often prolonging hospital stay and resulting in a poor cosmetic result.

APPROACHES TO CARDIAC STRUCTURES AND GREAT VESSELS FOR TRANSTHORACIC CANNULATION FOR BYPASS

Full Sternotomy

The most commonly used incision for access to the heart and anterior mediastinal structures is a sternotomy. A vertical skin incision over the sternum, staying below the manubrium, permits full division of the sternum and provides an unobstructed view of all anterior mediastinal structures and direct access from branches of the aortic arch down to the inferior vena cava (IVC) at the level of the diaphragm. This approach is necessary when the surgical procedure requires access to upper and lower mediastinal structures, such as the aortic arch and right atrium, branch pulmonary arteries, and right ventricle. Examples include a first-stage procedure for hypoplastic left heart syndrome, repair of truncus arteriosus, and pulmonary atresia with ventricular septal defect.

The incision in the pericardium is also vertical. If it is placed directly over the cardiac structures to be accessed, it can facilitate exposure, particularly when transatrial procedures to access the ventricles are being performed. By opening the pericardium to the right of midline and retracting the right side of the pericardium to the sternum, the ventricles fall away leftward, aiding exposure. Sutures to suspend the pericardium to the sternum are critical in children, and they should also be used to rotate the heart to facilitate exposure to the chamber or vessels required. When the right atrium and cavae need

exposure, suspension of the right-sided pericardial edge to the periosteum of the sternum is often required to visualize the lateral wall of the right atrium and inferior cava. If the left side of the pericardium is left unsuspended and is incised along the edge of the diaphragm to the apex, the entire ventricular mass will rotate away from the surgeon, facilitating exposure of the atrioventricular valves and interventricular septum to the level of the apex. A similar approach can be used to optimize exposure of the right ventricular outflow tract for surgery to correct tetralogy of Fallot. Here, the pericardium at the level of the great vessels is suspended to the periosteum, leaving the pericardial edge at the diaphragm unsuspended, facilitating the view of the ventricular septal defect through the ventriculotomy.

Limited Sternotomy Incisions

For many procedures, a full sternotomy is not necessary to provide adequate access to all the relevant structures of the heart. This is particularly true in infants and young children because their sternum and rib cage are pliable, which permits retraction with minimal force. Preoperative planning of the procedure includes determining which mediastinal structures will need exposure for the surgical procedure and for cannulation for cardiopulmonary bypass (CPB). With the availability of thin-walled, wire-reinforced, small-diameter cannulas for use in children, cannulation for CPB can often be achieved with minimal extension of the thoracic incision beyond that needed for the repair itself. These approaches usually provide exposure sufficient to use standard techniques for myocardial protection, such as cardioplegia and left ventricular venting. A full sternotomy is unnecessary when, for example, the intracardiac repair is accomplished via a right atriotomy, such as for repair of atrial septal defect, ventricular septal defect, or complete atrioventricular canal defect, and in transatrial repair of tetralogy of Fallot and mitral valve repair.²⁻⁴

Trans-Xyphoid Mini-Sternotomy

With the trans-xyphoid mini-sternotomy approach, the skin incision extends from the level of the areola (mid thorax) down to the tip of the xyphoid process (Fig. 108-1). By detaching anterior diaphragm attachments to the cartilaginous segment of the rib cage anteriorly, access is gained to the anterior mediastinum. Before

FIGURE 108-1 ■ A partial or limited sternotomy incision.

FIGURE 108-2 ■ The limited sternotomy allows cannulation of the ascending aorta and both cavae. Insertion of the inferior caval cannula through a separate skin incision keeps the cannula out of the way, and the incision can later be used for tube thoracostomy.

performing the partial sternotomy, blunt dissection is required to detach the pericardium and thymus from the sternum. A partial sternotomy can be performed with a saw, but in infants, heavy bandage scissors are sufficient for dividing the lower sternum. Once the partial sternotomy is completed, a narrow-blade retractor such as an army-navy retractor is used to lift the sternum anteriorly and cephalad to provide exposure to the ascending aorta for cannulation. The retractor should not be placed on the skin and subcutaneous tissue, because adequate exposure of the upper mediastinum will not be achieved and necrosis of the skin could occur from prolonged retraction. To expose the aorta, however, caudal and anterior traction must be placed on the pericardium. This maneuver requires that thymus attachments to the pericardium be divided, or mobility of the pericardium and aorta will be inadequate. The pericardial incision must be made to the right of midline, and the pericardium should be pinned to the right edge of the divided sternum to expose the right atrium and cavae. In most cases, cannulation of the ascending aorta and both cavae can be easily achieved with this approach. Insertion of the inferior caval cannula through a separate skin incision keeps the cannula out of the way, and the incision can later be used for tube thoracostomy (Fig. 108-2).

Midsternal Mini-Sternotomy

When the right ventricular outflow tract or aortic root must be accessed, the partial sternotomy approach may still be used, but usually the skin and sternal incisions need to be extended superiorly 1 or 2 cm above the level of the areola. In this case, traction sutures on the pericardium at the level of the pulmonary and aortic roots suspend these structures into view, permitting adequate

exposure. To assist with caval cannulation, traction sutures should be placed only on the right side of the pericardium, lifting both cavae toward the right side of the sternotomy. The cardiac structures are allowed to rotate and shift leftward, enhancing exposure to the right atrium, the left atrium via the right upper pulmonary veins, and the aortic root.

Anterior or Anterolateral Thoracotomy

An anterior thoracotomy has been advocated for surgical repair of atrial septal defect and occasionally ventricular septal defects.^{5,6} A meta-analysis of six case control trials found that intubation time and hospital length of stay were shorter using an anterolateral mini-thoracotomy over a median sternotomy, whereas cardiopulmonary and cross-clamp times were longer.⁷ Axillary incision have also been advocated for simple heart lesions using CPB.^{8,9}

For the anterolateral thoracotomy, the incision is made in the anterior fourth intercostal space (ICS), and in females great care must be taken to incise well below breast tissue. Dissection of the pericardial attachments to the sternum and thymus greatly facilitates exposure by permitting retraction of the pericardium down toward the diaphragm and bringing the ascending aorta closer into view. Direct cannulation of the ascending aorta is preferable to peripheral cannulation via the femoral or axillary artery because these vessels are small in children and stenosis at the cannulation site can result in claudication with exercise. Recently, more flexible cannulas, available in all sizes for pediatric use, have facilitated aortic cannulation. Some arterial cannulas can be introduced over a guidewire, which makes insertion easier and safer. The cavae can be cannulated directly, although the superior cava cannula is often best introduced via the right atrial appendage and directed retrograde into the superior vena cava (SVC). Aortic clamping to achieve cardiac arrest can be difficult with conventional arterial clamps, which were designed for application via a sternotomy. In small children, a bulldog clamp is sufficient for aortic occlusion, and for larger children and teenagers, flexible clamps are available. Cardioplegia can be delivered via a small flexible cannula inserted into the aortic root; some have advocated transthoracic insertion of a needle into the aortic root.

APPROACHES TO EXTRACARDIAC STRUCTURES IN INFANTS AND CHILDREN

Noncardiac thoracic surgery for the treatment of congenital cardiac defects or complications of cardiac surgery most often requires exposure to the posterior mediastinum. Exceptions include procedures to plicate the diaphragm, or for unifocalization of aortopulmonary collaterals, which requires dissection of the hilum of the lung. A posterolateral incision extending from just anterior to the tip of the scapula to the mid-posterior scapula provides access, through the fourth, fifth, or sixth ICS, to posterior mediastinal structures as well as the hilum of

FIGURE 108-3 ■ A left posterolateral incision extending from just anterior to the tip of the scapula to the mid-posterior scapula provides access, through the fourth, fifth, or sixth intercostal spaces, to posterior mediastinal structures, as well as to the hilum of the lung, pericardium, and diaphragm.

the lung, the pericardium, and the diaphragm (Fig. 108-3). If the upper half of the mediastinum needs exposure, an incision through the fourth ICS is optimal. For access to the hilum of the lung, the fifth ICS is optimal, and, for access to the thoracic duct at the level of the diaphragm, or to the central tendon of the diaphragm, a sixth ICS incision is optimal. The most common procedures in which a thoracotomy is performed routinely are operations on the thoracic aorta or branches, such as surgery for repair of coarctation of the aorta or for ligation of the patent ductus. Care should be taken to ensure that the appropriate interspace is entered, because exposure to the upper thorax can be very difficult in small children if the fifth interspace, or lower, is entered. Although counting ribs starting at the second rib, which has attachments of the anterior scalene muscle, can be done, external landmarks can also be used. A useful landmark is the position of the areola when the arm is extended over the head. With the arm extended, the interspace below the areola is usually the fourth ICS, and this landmark can confirm a particular interspace identified by other techniques. This method for identification of interspace is particularly useful in neonates and premature infants. Extensive division of the intercostal muscle is usually unnecessary in infants and small children. Adequate exposure can be obtained by separating the ribs, which are more flexible in this age group and entail less risk for fracture.

This same approach can be used for exposure of intra-pericardial structures such as the pulmonary trunk for pulmonary artery banding and even for intracardiac procedures. Exposure to the IVC for cannulation through a posterolateral thoracotomy can be difficult, however, and may require division of one rib posteriorly. Closure of the thoracotomy incision, as in adults, should be done in layers, approximating the serratus muscle and fascia separate from the latissimus dorsi muscle and subcutaneous tissue. This approach minimizes distortion of the chest wall muscles and provides the best cosmetic results as well.

A transaxillary approach has been described for ligation of the patent ductus, access to the transverse aortic arch and descending aorta, and, from the right axilla, closure of atrial septal defects. Either a transverse incision

is made over the third interspace between the fold of the pectoralis muscle and scapula or, as some have described, a vertical incision is made from the axilla down to the fourth ICS. The third interspace is then entered, which provides direct access to the distal aortic arch and arterial duct. However, exposure is limited and extension of the incision, if more exposure is required, is difficult. In experienced hands, however, this approach is adequate for ductus ligation, even in small infants, with a less visible incision.

Thoracoscopic Approach in Children

Because most cardiac procedures in children require CPB and intracardiac repair, port access for reconstruction has been applied almost exclusively to adult patients or, rarely, adult-size teenagers. Thoracoscopic procedures in children have been, for the most part, confined to approaches to noncardiac structures or to the pericardium. Examples include ligation of the patent ductus, division of vascular rings, creation of a pericardial window, and, more recently, insertion of pacer leads.^{10,11} More recently, total thoracoscopic approaches for repair of atrial and ventricular septal defects have been described.^{12,13} Much of the instrumentation has been adapted from other surgical applications, and the thoracoscopic procedures have involved primarily dissection and ligation or division with little reconstruction or suturing. Using induced electromyography to establish the location and local course of the recurrent laryngeal nerve may be of some benefit in infants and small children undergoing patent ductus arteriosus ligation or vascular ring procedures.¹⁴

Positioning and location of port incisions follow the principles of thoracoscopy or thoracotomy in adults. For access to the distal transverse aortic arch and descending aorta, the patient should be in a full lateral decubitus position. For access to anterior mediastinal structures, such as the anterior pericardium or thymus, a partial decubitus position with the thorax tilted toward a supine position is optimal. Usually, four incisions are required, two for the surgeon's instruments for the dissection, one for the scope and camera, and the fourth for the assistant to introduce lung retractors or occasionally a grasper or suction. As with any thoracoscopic procedure, the central port is used for the camera and the instrument ports are to each side of the camera port, separated by sufficient distance to prevent the scope from interfering with instrument movement. When a surgical robot is used to assist, the same port position is used, but the port for the lung retractor and suction is placed at the midaxillary line at the sixth or seventh ICS (Fig. 108-4).

For the approach to anterior mediastinal structures, the same arrangement is used with respect to the camera and instrument ports. In cases such as dissection of the right lobe of the thymus for thoracoscopic innominate artery suspension to relieve tracheal compression, the central port for the scope is placed at the anterior axillary line in the fourth ICS, and the two instrument ports are placed two or three interspaces to each side and 2 to 3 cm more anterior. A fourth port can be used for lung retraction and should be placed one or two ICSs lower toward

FIGURE 108-4 ■ Port position for robot-assisted thoracoscopic division of vascular ring. The scope and camera are introduced through the central port (C), and instruments are introduced through the other two ports for the robot's left arm (L) and right arm (R). (From Mihaljevic T, Cannon JW, del Nido PJ: Robotically assisted division of a vascular ring in children. *J Thorac Cardiovasc Surg* 125:1163–1164, 2003.)

the diaphragm so as not to interfere with instrument motion. For the anterior pericardium, the three ports are placed more inferiorly on the chest using the fourth or fifth ICS for the scope and camera, and the instrument ports one or two interspaces on either side.

CARDIOPULMONARY BYPASS IN CHILDREN

History

The use of extracorporeal circulatory techniques in the repair of congenital cardiac defects began in the 1950s, shortly after the concept of CPB appeared and a heart-lung machine was constructed. Gibbon repaired an atrial septal defect using the first heart-lung machine, which required 12 to 14 units of blood prime, in 1953.¹⁵ At approximately the same time, Lillihei and colleagues began using cross-circulation to repair a variety of defects in relatively young infants and children, including ventricular septal defects, atrioventricular canal defects, and tetralogy of Fallot, achieving a remarkable overall survival of greater than 60%.¹⁶ Shortly thereafter, Kirklin developed a pump oxygenator derived from Gibbon's earlier efforts.¹⁷ This device required approximately half of the original amount of fresh blood prime but also extreme care to prevent severe foaming of blood, which was lethal; nonetheless, the survival rate was 50%. These early reports prompted many subsequent investigations aimed at developing the scientific and technologic knowledge needed to successfully

undertake extracorporeal circulation in infants and children. In spite of these efforts, the morbidity and mortality associated with the use of CPB remained high throughout the 1960s.

The next major advance occurred in the early 1970s, when Castaneda and colleagues¹⁸ and Barratt-Boyes¹⁹ described the use of deep hypothermic circulatory arrest (DHCA) in infants. These techniques relied primarily on surface cooling, with exposure to the CPB circuit limited to a brief period of core cooling and rewarming, so that total CPB time was typically kept under 20 to 30 minutes. Progressive advances in the design of circuit components and perfusion techniques for infants and small children occurred throughout the 1980s and into the early 1990s. As a result, the "toxicity" associated with the use of CPB in infants declined significantly. Currently, lengthy and complex repairs, such as the arterial switch procedure for transposition of the great arteries and primary repair of tetralogy of Fallot, can be undertaken using CPB in neonates and very young infants and result in an overall mortality rate of less than 5%. Nonetheless, the morbidity associated with the use of CPB in infants and children is still widely held to be a major limitation to completely successful outcomes.

Differences between Pediatric and Adult Cardiopulmonary Bypass

There are many significant differences in circuit technology and the physiologic effects of CPB in neonates, infants, and small children compared with adults. The surface area and volume of the CPB circuit relative to

TABLE 108-1 Sample Scheme for Infant and Pediatric Oxygenators*

Oxygenator	Optimal Body Surface Area (m ²) [†]	Estimated Total Prime Volume [‡] (mL)	Membrane Surface Area (m ²)	Heat Exchange Surface Area (m ²)	Manufactured Recommendation Maximal Flow Rate (mL/min)

*Used under standard configuration.

[†]Assuming maximum 3 liter/min/m² flow rate.

[‡]Assuming use of standard configuration and usual tubing size and length for weight. KVAD, Kinetic-assisted venous drainage.

patient size and blood volume is much greater for neonates and infants. Arterial and venous cannulas are smaller but more likely to deform or obstruct the aorta or venae cavae. The placement of these cannulas can be different and more variable than in adults—for example, separate superior and inferior vena caval cannulas or initial placement of the aortic cannula in the pulmonary artery (with retrograde systemic perfusion via the ductus arteriosus) during stage I repair of hypoplastic left heart syndrome. To minimize hemodilution, the sizes of various circuit components and tubing diameters are kept as small as possible. Nonetheless, hemodilution that is equivalent to one to two blood volumes from the circuit prime and cardioplegia is fairly common in neonates and small infants (see Table 108-1).

DHCA, although used much less frequently than even a few years ago, is still used occasionally. Overall, pump flow rates can range from no flow (i.e., circulatory arrest) to more than 200 mL/min; mean arterial pressures can vary from 10 to 20 mm Hg during low-flow CPB to more than 50 mm Hg at full or high flow. Temperatures are typically lower in CPB for infants (core temperatures of 15° to 18° C for deep hypothermia; 22° to 25° C is used by some for many other complex repairs), and different blood pH management strategies may be used (i.e., alpha-stat versus pH-stat). In part because of these differences, the magnitude of neuroendocrine stress responses and systemic inflammatory responses to CPB, as well as their consequences, are generally believed to be more profound in neonates and infants than in adults.

Patient Factors

Patient-specific variables and the diverse pathophysiology associated with specific congenital cardiac defects further complicate CPB in neonates, infants, and small children. It is likely that neonates, in general, and particularly those who are premature or weigh less than 1.8 to 2.0 kg, comprise a high-risk group because of immature organ function and coexisting diseases such as sepsis, respiratory distress syndrome, and other congenital anomalies.²⁰ The immature myocardium may be similarly prone to CPB-related dysfunction for several reasons, including its relatively deficient (compared with in adults) contractile protein mass and organization of contractile

proteins, the presence of fetal contractile protein isoforms, immature calcium cycling (which occurs primarily via the sarcolemmal membrane as opposed to the sarcoplasmic reticulum, which is less abundant and less well organized), and fewer mitochondria.

Various aspects of congenital heart disease can mean additional complicating features. Hypertrophic and cyanotic myocardium is more likely to be injured by ischemia-reperfusion and other consequences of CPB.²¹⁻²⁴ Aortopulmonary collaterals, which can be particularly significant in various cyanotic lesions, may promote pulmonary dysfunction as a result of high flow on CPB, whereas steal from systemic perfusion can compromise the function of other organs, and collaterals to the coronary circulation can wash out cardioplegia and thereby hinder effective myocardial preservation. Pulmonary dysfunction after CPB may be more prevalent in infants with other routes of high pulmonary blood flow (e.g., truncus arteriosus, hypoplastic left heart syndrome, transposition of the great arteries) and in cyanotic infants.^{20,25} Diffuse organ dysfunction is likely to be more common in patients who were severely cyanotic and hypoperfused at the time of delivery or who required complex surgery in the early neonatal period. In the neonate who was compromised at the time of delivery or thereafter, most centers have found it beneficial to allow a period of stabilization of the circulation and recovery of organ function prior to undertaking CPB and cardiac surgery, using lesion-appropriate interventions such as prostaglandin E1, inotropic support, ventilatory strategies to balance systemic and pulmonary blood flow, and even extracorporeal circulatory support (see later). Post-CPB organ dysfunction (e.g., kidney, liver) can also be a source of morbidity in older (i.e., adult-age) patients with various forms of congenital heart disease complicated by long-standing cyanosis, low cardiac output, or high systemic venous pressures.

Differences in the Cardiopulmonary Bypass Circuit

A summary of the components of different-sized CPB circuits is shown in Table 108-1.

Oxygenators. Oxygenator systems for infants and children must function over a wide range of pump flow rates

(maximal flow rates range between 800 and 4000 mL/min, and they must be efficient over a range of flows equivalent to 0 to 250 mL/kg), temperatures (10° to 38° C), hematocrits (15% to 40%), and line pressures (because of different sizes of cannulas and tubing).

Virtually all current pediatric CPB applications use membrane-type oxygenators. The two main types are microporous (hollow-fiber or folded-membrane) and nonporous membrane oxygenators. The major advantage of microporous-type membranes is their ability to effect gas exchange with a relatively modest membrane surface area, typically in the range of 0.2 to 1.5 m², depending on the specific oxygenator and configuration. Major disadvantages include some blood-gas contact at the start of CPB (until protein accumulation blocks the 0.05- to 0.25-μm pores) and protein leakage across the membrane, along with the potential for gas embolization if negative pressure develops on the blood side of the artificial membrane. Nonporous oxygenator membranes, typically of the folded-sheet silicone-membrane variety, require a larger surface area to achieve gas exchange but do not accumulate or leak protein as readily and are therefore more often selected for longer-term circulatory support applications (e.g., extracorporeal membrane oxygenation).

There is a real need to minimize circuit priming volume to minimize hemodilution, blood product exposure, and the potential for fluid overload and edema.²⁶ Priming volume is usually defined as the volume of the membrane compartment plus the minimal amount required for the venous reservoir. Typical priming volumes of commercial membrane oxygenators range from approximately 225 to 375 mL when used in the open configuration. The Dideco Lilliput hollow-fiber membrane oxygenator (Dideco, Mirandola, Italy) is an example of one with a smaller prime volume (≈70 mL), but it is not available in an open-system configuration. More recently, oxygenators and arterial filters have been combined into one unit, further reducing priming volume (e.g., Quadrox-I Neonatal and Pediatric with integrated arterial filter, Maquet, Rastatt, Germany; or Capiiox FX05, Terumo Corporation, Tokyo, Japan). Various schema for achieving low priming volume and thereby reducing or avoiding the need for blood products as a component of the priming solution have been described.²⁷⁻³³

Pumps. Most pediatric circuits use roller pumps. Pump flow rate is governed by the revolutions per minute (rpm) of the pump head, the degree of occlusion produced by the rollers, and the internal diameter of the tubing. A significant advantage is that pump flow is relatively independent of resistive and hydrostatic forces in the circuit. However, adequate flow is highly dependent on proper setting of roller head occlusion (which also affects the degree of blood trauma and hemolysis), along with accurate knowledge of pump head speed (rpm) and tubing size. Failure to accurately account for any of these variables can lead to excessive or inadequate pump flow.

Tubing. Competing considerations govern selection of tubing size for infant and pediatric CPB (Table 108-2). The internal diameter needs to be large enough to permit

TABLE 108-2 Infant and Pediatric Cardiopulmonary Bypass Tubing

Tubing Diameter (inch)	Tubing Volume (mL/ft)	Flow Rate (mL/revolution)
3/16	5.0	7.4
1/4	9.7	13
3/8	21.7	27
1/2	38.6	45

the required full flow rate (see later) without inordinately increasing circuit line pressures. On the other hand, the tubing should be as narrow and as short as practical, to minimize priming volume. Some neonatal circuits use 1/4-inch tubing on both arterial and venous limbs, and most centers have further decreased the diameter of the arterial tubing to 3/16 inch; some use 3/16-inch tubing for both arterial and venous limbs (although vacuum-assisted venous drainage may be required in this case).²⁰ The pump is usually situated as close to the surgical field as possible to reduce tubing length, which is a major contributor to overall circuit volume.

Venous Drainage. As in adult circuits, venous blood usually flows from the patient to the venous reservoir of the CPB circuit by gravity. The level of blood in the venous reservoir serves as an important safety mechanism: it is a source of volume to increase arterial inflow and to assess the adequacy of venous return. If venous return and the level in the venous reservoir decline, the cause (e.g., unrecovered or lost blood in the surgical field, malpositioned venous cannulas, excessive capillary leak) can be identified, and interventions (e.g., decreasing pump flow rate, adding volume, adjusting operating table height, repositioning venous cannulas) can be performed.

Many venous reservoirs are rigid and used in a configuration that is open to the atmosphere. Advantages include ease of removing entrained venous air, free flow of venous drainage (i.e., no air lockage or buildup of pressure in the reservoir), integration of the cardiectomy reservoir (as opposed to having a separate reservoir for cardiectomy suction), and the ability to accurately measure reservoir volume via calibration lines on the side of the chamber. This last feature is a useful aid to assess the patient's intravascular volume and may therefore facilitate weaning from CPB. Major disadvantages of open, rigid venous reservoirs include the presence of a blood-air interface, which may promote blood trauma and activation of the coagulation, fibrinolytic, and inflammatory cascades (see later), and the need for a larger priming volume.

A soft, collapsible venous reservoir bag that expands and contracts in relationship to overall blood volume, venous return, and arterial inflow rate is used with increasing frequency in infant CPB. Advantages include the absence of direct blood-air contact and the fact that air is not entrained if the venous reservoir becomes empty, which collapses the bag. A major disadvantage can be the inability to accurately measure venous reservoir

volume or to recognize subtle but important changes in venous return. Other relative disadvantages compared with rigid reservoirs include the need for a removal mechanism if air is entrained, the need for a separate cardiectomy suction reservoir, and the fact that venous drainage will be significantly reduced if pressure builds up as a result of overfilling of the reservoir with blood volume or air.

Vacuum-assisted venous drainage has been used for pediatric patients.^{20,28,34-36} Although this has not been well studied in a controlled or prospective fashion, advantages may include the ability to reduce total circuit volume by using lower venous reservoir volume and $\frac{3}{16}$ -inch venous tubing, improving operating conditions to some extent by allowing use of smaller venous cannulas, and improving venous drainage through the small cannulas and tubing. Theoretically, the improvement of venous drainage could lead to reduced tissue and organ edema and congestion, improved organ function, and reduced inflammatory activation (e.g., via endotoxin release from congested, hypoperfused intestine). A major potential complication of vacuum-assisted venous drainage is venoarterial air embolism.³⁷⁻⁴¹

Arterial Cannulas. Issues regarding cannula size are much more significant in infants and small children than in adults. Arterial cannulas for neonates and small infants must be of sufficient size to permit appropriate arterial inflow rates at reasonable line pressures, with minimal shearing or jetting of blood flow (which can damage the vessel intima, aortic valve, or blood elements), yet small enough to fit in small aortas without obstructing aortic flow (Table 108-3). Small cannulas (i.e., 8 Fr) with a thin-walled, reinforced design that prevents cannula kinking and allows a larger luminal diameter for a given external diameter have become popular choices for infant bypass (Biomedicus, Medtronic, Minneapolis, MN). Care also needs to be taken not to kink or compress the infant's pliable aorta by the location and orientation of the aortic cannula and its tubing. As noted, the cannula itself can significantly obstruct flow in the vessel around the cannula. Location of the tip can direct blood flow toward or away from specific vessels; for example, locating and directing the tip more distally toward the transverse arch may reduce flow through the right carotid artery or favor lower body perfusion at the expense of cerebral perfusion and optimal brain cooling.⁴²

Certain congenital cardiac lesions require unique aortic cannulation sites. For example, the aortic cannula

is typically placed more distally in the aorta for repairs that involve extensive proximal aortic surgery, such as the arterial switch procedure for transposition of the great vessels; this distal location may alter distribution of blood flow to the carotid vessels. Repair of interrupted aortic arch requires two arterial cannulas, one in each segment of the aorta (perfusing the head and lower body, respectively). The aortic cannula is placed in the pulmonary artery at the beginning of CPB for stage I repair of hypoplastic left heart syndrome because of the typically diminutive size of the ascending aorta in this lesion. The distal pulmonary arteries are occluded with tourniquets and the aorta is perfused via the ductus arteriosus until the aortic reconstruction is completed, at which time the cannula is repositioned in the neo-aorta. The aortic cannula can also be placed into a side graft, which is anastomosed to the innominate artery, for arch reconstruction using antegrade cerebral perfusion.

Unlike in adults, femoral arterial cannulation for CPB is not usually a viable option in infants and small children (weighing less than ≈ 10 to 15 kg), because small vessel size precludes inserting an arterial cannula that is large enough to allow arterial inflow rates that are sufficient to completely meet metabolic needs (see later). In small infants (without recent sternotomy), the neck vessels are the preferred extrathoracic cannulation sites (see later). However, as a resuscitative measure in emergent situations (e.g., cardiopulmonary arrest in the cardiac catheterization laboratory, particularly when femoral vascular access is already in place), insertion of smaller perfusion cannulas in the femoral artery has often been life-saving in terms of facilitating rapid establishment of extracorporeal support. Femoral access is performed occasionally for older children, either electively, when there is concern that a cardiac chamber or vascular conduit lies immediately beneath the sternum, or emergently, when one of these structures is entered inadvertently during the dissection.

Venous Cannulas. Choice and location of venous cannulas can also be more complex and variable than is typically the case in adults, and variations in venous anatomy and drainage as well as the operative approach must be taken into account. Venous cannulas are available in a variety of sizes and with design features for particular indications (Table 108-4). For example, thin-walled cannulas with multiple side holes enhance venous drainage; right-angled tips are frequently used in the SVC to improve alignment (and therefore drainage) and minimize impact on the surgical field; metal-tipped, to prevent kinking; straight, short-tipped in the IVC, to limit hepatic venous obstruction.

Overall, most repairs use separate SVC and IVC cannulas to achieve maximal collection of venous return and to minimize interference with the operative field. Common variations in venous anatomy that can complicate venous cannulation and must be taken into account include left or bilateral SVCs, azygous or hemiazygous continuation of the IVC, and direct drainage of the hepatic veins into the atrium. A single atrial cannula is frequently used when DHCA is planned; in this case, the venous cannula is removed after the patient is adequately cooled, to provide a clear operative field.

IVC, Inferior vena cava; SVC, superior vena cava.

Regardless of location, it is important that the cannula be appropriately sited and that it cause as little obstruction to venous drainage as possible. Poor venous drainage may be difficult to detect and is more likely to occur in patients with complicated venous anatomy. The consequences of impaired venous drainage and increased venous pressures are likely to be magnified during CPB because arterial perfusion pressure is frequently reduced. Obstruction of the SVC may promote cerebral edema and otherwise increase the risk of brain injury by decreasing cerebral blood flow (CBF) and hindering effective brain cooling. Many physicians find monitoring of SVC pressure by a catheter placed in the internal jugular vein useful to detect possible SVC obstruction in this setting. In addition, the patient's head and face should also be inspected at regular intervals during CPB for the appearance of congestion or swelling. It is likely that monitoring CBF velocity using transcranial Doppler methodology might be useful in this regard. A drop in cerebral near-infrared spectroscopy (NIRS) saturation may herald poor

SVC drainage and need for cannula adjustment. IVC obstruction will increase lower body venous pressures and potentially decrease hepatic, renal, or mesenteric perfusion; isolated hepatic vein obstruction can also occur. Consequences can include hepatic dysfunction, renal dysfunction, ascites, and perhaps increased inflammatory consequences of mesenteric congestion.^{43,44} IVC obstruction during CPB can be difficult to detect and should be suspected whenever there is development of ascites, decreased urine output, or impaired venous return.

Filters. Almost all applications use 0.2- μ m filters in the gas inflow lines to prevent bacterial or particulate contamination. Similarly, all crystalloid prime and cardioplegia solutions are passed through 0.2- μ m filters prior to final addition to the CPB circuit. A 20- or 40- μ m filter is used on the cardiotomy suction return line to remove macro- and microaggregates and other debris from the blood returning from the surgical field. Exogenous blood is also filtered (typically through a 40- μ m blood filter) before it is added to either the pump circuit or to cardioplegia. Specific removal of blood polymorphonuclear leukocytes using leukocyte-depleting filters placed in-line on the CPB circuit (which typically reduces circulating leukocyte counts in the patient by $\approx 75\%$) is advocated by some centers as a significant means to reduce reperfusion injury.^{25,45}

Use of an arterial filter (40 μ m) is somewhat more controversial. Many consider arterial filtering essential to limit the microemboli and amount of other debris from platelet and leukocyte microaggregates, traumatized blood elements, fat, and other sources, particularly because these might contribute to post-CPB neurologic injury and damage to other organ systems. Some physicians do not feel strongly about these issues and omit arterial line filters, at least in part to reduce priming volume and hemodilution.²⁰ As mentioned previously, there are now oxygenators with integrated arterial filters.⁴⁶

Cardiopulmonary Bypass Prime. The priming volume of even the smallest neonatal and infant CPB circuits is usually equivalent to approximately 1.5 to 3 times the patient's blood volume. Thus, dilution of red cells, clotting factors, and other plasma constituents is potentially of far greater magnitude than in adults. Physiologic crystalloid solutions (e.g., Normosol-R, Hospira, Lake Forest, IL) are the major component of CPB priming solutions in infants and children; colloidal primes are used infrequently. Significant additions to the infant CPB prime include packed red blood cells (or occasionally whole blood), as well as fresh-frozen plasma or other colloids such as albumin.

Other agents that may be included in the pump prime include mannitol, steroids, heparin, and buffers (e.g., sodium bicarbonate or tris[hydroxymethyl]aminomethane [THAM]). Mannitol is used primarily for its osmotic properties and is intended to reduce organ and cellular edema as well as to promote diuresis and thereby contribute to renal protection. The osmotic diuresis may be particularly beneficial in some congenital cardiac

operations in which a substantial amount of hemolysis from blood trauma caused by cardiomy suction and high pump flow rates can occur. Stabilization of cellular membranes and various antioxidant properties, including radical scavenging, have also been attributed to mannitol. The significance of any of these effects has not been proven in pediatric CPB. Steroids are used to reduce inflammatory effects of CPB (see later).

The use of albumin or other colloid to prime CPB circuits is also controversial.⁴⁷⁻⁴⁹ There is evidence that reduced plasma protein concentrations and diminished plasma oncotic pressure can reduce lymphatic flow and increase capillary leak in the lung and other vascular beds.⁵⁰⁻⁵³ Although fluid balance and weight gain were favorably influenced, a recent study that randomized pediatric CPB patients to crystalloid or colloid prime did not demonstrate significant differences in mortality or in length of mechanical ventilation, intensive care unit stay, or hospital stay.⁵³ These results are similar to those obtained in adults, where albumin does prevent CPB-induced reductions in colloid oncotic pressure and lung water accumulation, but it appears to have little effect on overall outcome or measures of pulmonary, myocardial, or renal function. Synthetic colloids are available but have not demonstrated benefits in adults.

Hemodilution. As noted earlier, some centers have gone to substantial lengths to modify circuit design to reduce the degree of hemodilution associated with infant CPB and decrease the use of exogenous blood and other products. These modifications have included the use of the smallest possible tubing, cannulas, and oxygenators; altered orientation of the CPB circuit to decrease tubing length; vacuum-assisted venous drainage to improve return through the small cannulas and tubing; and omission of arterial filters. Resultant priming volumes in the range of 180 to 250 mL have been reported. Ultrafiltration techniques (see later) are also used to offset the hemodiluting effects of CPB and thereby reduce the requirement for donor blood and blood products. With the possible exception of ultrafiltration, there is no evidence that edema, the inflammatory response to CPB, or overall outcome is improved by these measures, and, at present, it remains difficult to avoid the use of exogenous blood or blood products in patients who weigh less than approximately 10 kg.

Both packed red cells and whole blood have been used to ensure age-, lesion-, and temperature-appropriate hematocrit during CPB. Packed red cells are readily available and are probably used by most centers to increase and maintain hematocrit during CPB. A major disadvantage of whole blood compared with packed red cells is the higher glucose load that accompanies whole blood; hyperglycemia may increase the risk of brain injury during cerebral ischemia. On the other hand, whole blood more effectively maintains plasma factor concentrations, which can be significantly reduced by CPB in these patients (see later). Questions about the actual oxygen carrying and delivery capacity of stored red blood cells have been raised.⁵⁴ Increased duration of blood cell storage has been related to postoperative morbidity.⁵⁵

The optimal hematocrit for neonatal and infant CPB remains controversial. Perhaps the most important consideration is the temperature and flow rate that are to be used (e.g., deep hypothermia, low flow, or circulatory arrest). More profound degrees of hypothermia are used in pediatric patients to suppress metabolic demands and increase tolerance to periods of low flow (25° to 18° C) or absent flow (15° to 18° C). Although the oxygen-carrying capacity of hemoglobin increases at lower temperatures, its ability to donate oxygen to the tissues is also reduced. Moreover, the increase in blood viscosity that accompanies hypothermia is a significant impediment to microcirculatory flow and can lead to sludging and regional ischemia. The nonpulsatile flow patterns typical of most CPB applications may also decrease microcirculatory flow, particularly in the setting of increased viscosity. It is also important to note that the oxygen-carrying capacity of the non-red cell fluid component of blood (i.e., plasma) increases at decreasing temperatures because of the increased solubility of gas in the liquid phase that occurs as temperature declines; as a result, the net effect of hemodilution during hypothermia is to improve microvascular flow and oxygen delivery.

Despite these theoretical considerations, the optimal and maximal tolerable levels of hemodilution for a given degree of hypothermia are not established. Normovolemic hemodilution with hematocrit levels down to 15% is believed to be well tolerated during normothermia in terms of cerebral and myocardial function as long as blood pressure, oxygenation, and cardiac output are maintained.^{56,57} Long-standing practice at many centers has been to aim for hematocrit levels in the 18% to 22% range during deep hypothermic CPB, and this is based on the aforementioned improvements in blood rheology and overall oxygen-carrying capacity that accompany the combination of hemodilution and hypothermia. Animal studies and reports of children of the Jehovah's Witnesses faith undergoing hypothermic CPB suggest no detectable effect on overall outcome or cerebral or cardiovascular morbidity at hematocrits in the range of 10% to 18% when a low temperature, perfusion pressure, and flow rate are maintained.⁵⁷⁻⁶⁰ Hematocrits of 10% or less in infants have been associated with acidosis and other evidence of inadequate oxygen delivery.

More recent evidence has cast doubt on the safety of very low hematocrits during hypothermic CPB in infant patients. In experimental infant CPB models, higher hematocrit (in the 25% to 30% range) has been associated with enhanced preservation of brain high-energy phosphates, intracellular pH, tissue oxygenation, maintained capillary density and microvascular flow, reduced leukocyte activation, and reduced neurologic injury.⁶¹⁻⁶³ A recent clinical study that randomized infants to either a low hematocrit (mean hematocrit, 22% $\pm$ 3%) or high hematocrit (28% $\pm$ 3%) strategy at the start of low-flow hypothermic CPB found lower postoperative cardiac index, higher serum lactate, and higher total body water in the low hematocrit group. At 1 year, overall neurologic evaluations and mental development index scores were similar in the two groups, but the low hematocrit group had significantly lower psychomotor development index scores.⁶⁴ Our current practice is to aim to keep the

hematocrit between approximately 25% and 30% during all types of CPB. A hematocrit level at the onset of low-flow CPB of approximately 25% was associated with higher psychomotor development index scores and reduced lactate levels.^{65,66} In addition to any direct effects, it is likely that the somewhat higher hematocrit provides some degree of safety margin against other problems with perfusion, collaterals, and alterations in cerebral autoregulation and CBF.^{59,65-70} However, similar variations in patient age, anatomy, collaterals, flow rate, pH strategy, and cooling, for example, make it impossible to pronounce a single optimal hematocrit for infants or children.

The optimal hematocrit for weaning from CPB is also controversial. The overall goal is adequate systemic oxygen delivery. Our current practice is to aim for hematocrits in the range of 25% to 30% during rewarming and at termination of CPB. These levels (and perhaps even somewhat lower) are likely to be well tolerated by patients who have good myocardial function, minimal or no hemodynamic lesions, and a physiologic repair with normal oxygen saturation at the conclusion of their surgery. Consideration should be given to increasing hematocrit to improve oxygen-carrying capacity and oxygen delivery in patients with reduced myocardial function or palliative or staged operations that result in cyanosis. In these cases, hematocrits of 40% or even slightly higher may be beneficial, but definitive data are lacking.

Pump Flow Rates during Pediatric Cardiopulmonary Bypass. Optimal pump flow rates for pediatric CPB are, as for adults, based on considerations of adequate systemic oxygenation, oxygen delivery, and organ perfusion at normothermia as assessed by oxygen consumption and metabolic rate, mixed venous oxygen saturation, acid-base balance, and lactate production.⁷¹ These are typically indexed to body weight. The higher metabolic rate of neonates and infants (≈ 1.5 - to 2.5 -fold greater than that of adults) mandates proportionately higher flow rates during normothermic CPB (Table 108-5).

Heparinization. The approach to anticoagulation during pediatric CPB is similar to that for adults. Heparin is administered in a dose of approximately 4 mg/kg (400 U/kg) prior to initiation of bypass, either directly into the right atrium or into a central venous catheter; teams at some centers include a portion of the total heparin dose in the CPB pump prime. Confirmation of heparin injection by blood aspiration, as well as the

adequacy of heparin effect, should be performed before beginning CPB. The activated clotting time (ACT) is the primary method of monitoring the efficacy of heparin anticoagulation (and reversal) in infants and children. Typical guidelines require an ACT of greater than 400 seconds before initiating CPB, and ACT should be maintained between 400 and 600 seconds during CPB to prevent activation of blood coagulation pathways and clot formation. Inadequate concentrations of heparin are believed to be a major contributor to excessive activation of the coagulation and fibrinolytic systems.⁷² Other methods of monitoring heparin effect, anticoagulation, and clotting parameters, such as blood heparin concentration and thromboelastography, are adjunctive at present and used mainly to assess residual heparin activity and diagnose and treat coagulopathies after termination of CPB.⁷³ Heparin brand and formulation will affect the level of anticoagulation and even the amount of postoperative bleeding.^{74,75}

Although substantive data are scant, there is some evidence that, generally, neonates and young infants are more sensitive to the effects of heparin administered for CPB and that the efficacy and duration of heparin-based anticoagulation is significantly more variable in neonates and young infants.^{72,76-78} Potential mechanisms include the variable and generally lower levels of both procoagulant and anticoagulant factors present during the first few months of life and in some patients with congenital heart disease.⁷⁹⁻⁸² The degree of hypothermia, amount of hemodilution, and relative immaturity of drug metabolism can also contribute to an increased and prolonged heparin effect in infants. Heparin resistance, on the other hand, is seen infrequently in infants, although sporadic examples resulting from recent heparin exposure or antithrombin III deficiency do occur. Heparin-induced thrombocytopenia and thrombosis appear to be less common in infants and children than in adult heart surgery patients, but the incidence may increase as the number of children who are repeatedly exposed in the operating room, catheterization laboratory, and other sites continues to increase.^{83,84} There is at present only limited and anecdotal experience with the use of heparin alternatives such as bivalirudin, hirudin, and argatroban, for anticoagulation during pediatric CPB.⁸⁵⁻⁸⁷

Heparin Reversal. Protamine sulfate is administered at the end of CPB to reverse the anticoagulant effects of heparin. As with heparin, there is little prospective, controlled information about the dosing of protamine in neonates and infants. Protamine dosing is usually based on body weight (3 to 4 mg/kg) or in a ratio to the heparin dose (milligrams-to-milligrams) of 1:1 or 1.3:1; in vitro titration to neutralize heparin in a patient sample is also used by some physicians. In general, the target ACT after protamine administration is within approximately 10% of the pre-CPB baseline. The first two empirical methods usually result in relative protamine excess, which is intentional because of greater heparin sensitivity and duration in infants and because of other factors that may potentiate heparinization, such as hemodilution, hypothermia, and delayed metabolic clearance. However, as with adults, there is evidence that empirical protamine dosing is

TABLE 108-5 Estimated Flow Rates for Normothermic Infant and Pediatric Cardiopulmonary Bypass

Body Weight (kg)	Flow Range (mL/kg/min)	Usual Full-Flow Rate (mL/kg/min)
<3	150-200	200
3-10	125-175	150
10-15	120-150	125
13-30	80-120	100

associated with excess protamine administration and perhaps greater blood loss and transfusion requirements as compared with doses that directly measure blood heparin using titration or other methods.^{77,78,88,89} Another argument against empiric dosing is that relatively small excesses of circulating protamine compared with heparin may have direct antiplatelet effects that can exacerbate bleeding after CPB.⁹⁰

Typically, the drug is administered slowly over approximately 10 minutes. For unclear reasons, severe hypotensive, pulmonary vasoconstrictive, or anaphylactic/anaphylactoid reactions to protamine are uncommon in infants and children.⁹¹ Of these, hypotension is most frequent, occurring in between approximately 1.5% and 3% of protamine administrations. It is dependent on dose and rate of administration, most likely resulting from histamine release, usually fairly mild and transient, and responsive to volume replacement or calcium administration. Severe pulmonary vasoconstriction appears to be much less common than in adults, maybe as a result of complement activation or pulmonary thromboxane release, and can be particularly troubling in patients with depressed contractile function.

Initiation of Pediatric Cardiopulmonary Bypass

CPB is initiated once the arterial and venous cannulas are correctly positioned and connected to the circuit, the absence of air in the arterial line (especially at the connection between cannula and circuit tubing) is confirmed, and adequate anticoagulation is established. Under most circumstances in neonates and infants, arterial inflow is begun slowly and then the venous line is unclamped. Rapid onset of bradycardia and loss of myocardial function can ensue when a cold prime is used. Therefore, when using either normothermic or cold pump primes, full flow is usually reached fairly rapidly in neonates and infants to ensure adequate systemic perfusion and oxygen delivery. When it is important to keep the heart beating and potentially ejecting, prime electrolyte concentrations—specifically calcium and potassium—are usually normalized, along with the temperature of the prime solution, so as to maintain myocardial function and prevent myocardial distention during the initiation of bypass. Compromised venous drainage can also distend the heart and promote myocardial damage.

Large collateral vessels arising from the arterial tree (as can be seen in many forms of cyanotic heart disease, including tetralogy of Fallot and pulmonary atresia), patent ductus arteriosus, and surgical aortopulmonary shunts can promote runoff from the systemic circulation during CPB and thereby reduce perfusion pressure, effective organ (i.e., brain, heart, kidneys) blood flow, and cooling despite seemingly adequate total pump flow. Surgical control and effective occlusion of large aortopulmonary collateral vessels, surgical shunts, and the patent ductus arteriosus is accomplished immediately before or shortly after commencing CPB. Significant aortopulmonary collateral vessels that are not important sources of pulmonary blood flow or contributors to arterial oxygenation can be coil-occluded in the cardiac catheterization

laboratory before surgery, which will also decrease the volume load on the systemic ventricle.

Monitoring during Pediatric Cardiopulmonary Bypass

Circuit Monitoring

Important CPB circuit variables include arterial line pressure, pump flow rate, oxygenator gases, and temperature. Arterial line pressure is measured via a pressure transducer placed in the arterial inflow limb. Line pressure can be substantially higher than patient arterial pressure because of the driving pressure required to achieve adequate flow through small-diameter infant arterial cannulas and tubing, and it is typically in the range of 225 to 260 mm Hg at mean arterial pressures of 40 to 60 mm Hg. Excessively high arterial line pressures (>300 to 400 mm Hg) can result from tubing or cannula obstruction or cannula malposition and can result in circuit rupture. Many circuits include a sensor on the oxygenator reservoir to detect critically low volume levels and a sensor on the arterial line to detect air.

The flow output of roller pumps is governed by roller head rpm, occlusion pressure, and the internal tubing diameter. Pump flow rate on roller pumps is not measured directly but rather *calculated* by the perfusionist (or electronics on the pump) based on these variables. Because the flow output of the pump is not measured directly, incorrectly measuring or inputting rpm, tubing size, or occlusion, as well as possible shunts in the circuit, can lead to potentially harmful perfusion errors (either increased or decreased). Unexpectedly low or high mean arterial pressure for the calculated flow rate may be the first clue to these possibilities. In the case of low flow in particular, abnormal biochemical variables result if the condition is of sufficient magnitude and duration (see later).

Oxygenator gases can include oxygen, air, and carbon dioxide. Continuous in-line monitors of pH, PO₂, and PCO₂ are used frequently. The gas “sweep speed” (flow rate) and oxygen concentration delivered to the oxygenator are controlled with a flowmeter or blender and measured with appropriate electrodes. Starting sweep speeds are usually at a ratio to pump flow rate of 1:1 for membrane oxygenators. However, the variability in pump flow rates, temperatures, and blood gas management strategies leads to wide variations in gas flow and composition in pediatric patients. pH-stat management can require altered gas sweep rates and the ability to add and precisely control carbon dioxide in the sweep gas.

Thermistors measure temperatures of the water bath and heat exchanger, along with arterial and venous blood temperatures. The temperature gradient between the patient and perfusate should not exceed 10° C. This can be especially important during rewarming to prevent formation of gaseous bubbles and emboli that result from decreased gas solubility as fluid temperature increases.

Patient Monitoring

Monitoring of mean arterial pressure is required during CPB and is most often accomplished via catheters in

either the radial or the femoral arteries. Arterial catheter location can occasionally be governed by considerations such as prior surgical or shunt (e.g., Blalock-Taussig) sites and the current lesion and planned operation. Femoral arterial pressure monitoring (with or without concomitant radial arterial monitoring) is preferred by some for aortic reconstructions and for increased reliability when deep hypothermia is planned, particularly in small infants. Left atrial and SVC or right atrial filling pressures are also measured routinely, depending on the surgery.

Nasopharyngeal, esophageal, and rectal temperatures are measured with appropriate thermistors. Nasopharyngeal or tympanic membrane temperatures are most often used and are probably the most accurate in terms of tracking brain temperature, although no extracranial site is truly reliable in this regard.⁵⁷ Rectal (or occasionally bladder) temperature is used to monitor core temperature. Esophageal temperature reflects aortic temperature and does not correlate well with core or brain temperatures.

Arterial and venous blood gases should be measured within 5 to 10 minutes after commencing and then at 15- to 30-minute intervals for the remainder of CPB but more frequently if there is evidence of compromised perfusion. In addition to pH, PO₂, and PCO₂, most analyzers can use the same samples to simultaneously measure hematocrit and serum electrolyte levels, including levels of sodium, potassium, and ionized calcium. Many centers favor allowing or even promoting (e.g., via the chelating effects of citrate in added blood products) reduced ionized calcium during CPB in an attempt to reduce the contribution of that cation to reperfusion injury. Ionized hypomagnesaemia, another potential contributor to ischemia-reperfusion damage and dysrhythmias, has been found after pediatric CPB, although its clinical significance is unclear.^{92,93} Increasing blood lactate concentrations before and shortly after pediatric CPB have been suggested to correlate postoperative morbidity and mortality.⁹⁴

The oxygen saturation of venous blood (SVO₂) is an important index of tissue perfusion, and it should be measured from venous blood samples at intervals as discussed in the previous paragraph and also continuously via a calibrated in-line monitor on the venous line. Optimal and minimal acceptable values for SVO₂ during CPB, particularly as temperature and flow rate decrease, are not well defined. At normothermic or near normothermic temperatures, SVO₂ can be interpreted as is done in non-CPB situations, and hence low values (less than ~60% to 70%) should raise concern about inadequate tissue oxygen delivery (e.g., inadequate flow, low hemoglobin). The development of shunting around major vascular beds that may occur as a consequence of CPB, in addition to any preexisting collateral vessels, may increase SVO₂ in an artifactual way; in other words, some degree of organ hypoperfusion may exist despite what appear to be acceptable SVO₂ values. At deeper levels of hypothermia, dissolved oxygen contributes an increasing proportion of total oxygen delivery, and the increased affinity of hemoglobin for oxygen impairs transfer from hemoglobin to tissue.⁹⁵ As a result, the interpretation of SVO₂ during deep hypothermia becomes more problematic,

and it may be prudent to require substantially higher levels of SVO₂ (>90%) when this measure is used to infer the adequacy of perfusion during deep hypothermic CPB.

Cerebral saturation measured by NIRS has been used as a surrogate for SVO₂ and, therefore, tissue perfusion. Cerebral NIRS correlates with SVC saturation.⁹⁶ Decrease in cerebral NIRS can be a warning of decreased cerebral perfusion. Periods of diminished intraoperative and perioperative cerebral saturation, as measured by NIRS, has been related to compromised neurodevelopmental outcome and abnormalities in cerebral magnetic resonance imaging.⁹⁷ Flank saturation measured with NIRS can also be used to alert to decreased tissue perfusion to the lower body during bypass.

Frequent monitoring of blood glucose and efforts to maintain it in the normoglycemic range are important during CPB in neonates, infants, and children. The major cause of hypoglycemia appears to be limited hepatic glycogen stores and gluconeogenic capability, especially in neonates, and perhaps also in cyanotic and malnourished (e.g., because of congestive heart failure) infants and young children. Failure to provide exogenous glucose can result in severe hypoglycemia and neurologic injury. The potential neurologic consequences of hypoglycemia may be exacerbated by hypocarbia, which seems to lower the threshold for hypoglycemic neuronal damage, and by patient lesions (e.g., aortopulmonary collaterals) and bypass strategies that independently reduce cerebral autoregulation or CBF (or both).⁹⁸⁻¹⁰⁰

Hyperglycemia can also be a frequent occurrence during pediatric CPB. Blood glucose may increase because of an increased supply from exogenous sources such as intravenous fluids and cardioplegia, or because of reduced glucose uptake, which is primarily caused by increases in stress hormones such as cortisol, growth hormone, and catecholamines that counter the effects of insulin.¹⁰¹ Additionally, deep hypothermia can also suppress glucose-stimulated insulin secretion during hypothermic CPB and for at least a few hours thereafter. Hyperglycemia can potentiate cerebral ischemia-reperfusion injury under a variety of circumstances in infants and children¹⁰²⁻¹⁰⁴ and a trend is seen toward similar results in pediatric CPB patients, although these data are largely retrospective and uncontrolled.^{98,105} Proposed mechanisms of hyperglycemic-ischemic brain injury include hyperosmolar cellular swelling from glucose loading and promotion of lactic acidosis or increased intracellular acidosis caused by increased anaerobic glycolytic flux.

However, this issue remains controversial. Increased blood glucose concentration may be important for adequate brain glucose delivery when CBF and autoregulation are impaired. There was only a weak correlation between blood glucose with brain creatine kinase (CK-BB) levels and no correlation with neurodevelopmental outcome in the Boston Circulatory Arrest study, and there was some evidence that post-CPB hyperglycemia was in fact protective, particularly against seizures, which are associated with worse neurodevelopmental outcomes.^{106,107} There are also substantial data in a variety of non-CPB animal models that pre-ischemic

hyperglycemia may protect immature brain from hypoxia, asphyxia, or hypoxia-ischemia.¹⁰⁸⁻¹¹¹ One important caveat is that these studies were conducted almost exclusively in immature rat models where circulation and ventilation were unsupported, and some of the protective effect of hyperglycemia may have resulted from better maintenance of the circulation or ventilation in hyperglycemic animals (an effect that would be largely irrelevant during CPB).

Further complicating this issue are reports suggesting that relatively modest degrees of hyperglycemia were associated with worse overall outcome in a variety of circumstances, including adult cardiac surgery and in at least some adult and pediatric patients under intensive care, and that tight glucose control could be beneficial.¹¹²⁻¹²⁰ Particularly in the case of adult cardiac surgery patients, at least some of the benefit appeared to be obtained in diabetic (and perhaps prediabetic) patients and to involve risks and complications not typically associated with infant congenital heart surgery.¹²¹⁻¹²³ However, additional and more recent analyses have called this conclusion into question, with a number of studies suggesting that moderate degrees of hyperglycemia are not associated with worse outcome and that tight control may in fact be detrimental.^{114,117,124-126}

In 2012 the *New England Journal of Medicine* published the results of a randomized controlled trial of tight glycemic control compared with standard care after pediatric cardiac surgery. Investigators found low hypoglycemia rates but were not able to demonstrate changes in mortality, infection, or organ failure between the two groups.¹²⁷

Hypothermia

Hypothermia continues to be the mainstay for protection of the brain and other organs during CPB. Its major and most pervasive effect is to decrease metabolic rate and consequently decrease metabolic demand for oxygen and other substrates. During ischemia, hypothermia slows consumption of high-energy phosphate compounds and also maintains them intracellularly, thereby facilitating recovery of adenosine triphosphate (ATP) and phosphocreatine during reperfusion. Hypothermia delays loss of ionic homeostasis during ischemia, particularly entry of sodium and calcium and resultant cellular edema, by energy-dependent, energy-independent, and membrane-stabilizing mechanisms.¹²⁸ Reduced amounts of free-radical generation, inflammatory cytokine production, white cell activation, and leukocyte adhesion molecule synthesis have all been associated with hypothermia or hypothermic CPB. Hypothermia suppresses release of excitatory amino acid neurotransmitters during ischemia and reperfusion, which is likely to be an important cerebral protective mechanism, especially in neonatal and immature brains.^{107,128}

Low-Flow Hypothermic Cardiopulmonary Bypass

The reductions in metabolic rate produced by hypothermia allow CPB flow rates to be reduced, thereby reducing the amount of blood returning to the heart and

improving surgical conditions. Most centers use values of approximately 50 mL/kg/min or 0.70 liter/min/m² for low-flow CPB. Studies in adults and children have suggested the relative safety, particularly in terms of cerebral protection compared with DHCA, of this range of low-flow CPB in combination with hypothermia.^{57,71,129-131}

Further reductions in pump flow to one quarter or less of normal may be used at deep levels of hypothermia (<18° C). However, there is no agreement on what a safe degree of flow reduction might be for a given temperature in infants and children. Kern and colleagues⁷⁰ have suggested that the critical pump flow rate in terms of the crucial juncture at which cerebral metabolism becomes flow dependent is between approximately 30 and 35 mL/kg/min at moderate hypothermia (26° to 29° C) and between 5 and 30 mL/kg/min during deep hypothermia (18° to 22° C). The bulk of evidence suggests that cerebral autoregulation is markedly diminished or absent at temperatures below 20° C, and hence CBF becomes pressure-passive at very low temperatures during CPB in infants.^{57,67,70} Burrows and Bissonnette showed that a significant percentage of neonates and infants who undergo low-flow CPB (<22% of normal pump flow) have no detectable CBF as measured by transcranial Doppler and require higher perfusion pressures to reestablish CBF.¹³² Similar results have been found by others at flow rates typical during profound (14° to 20° C, nasopharyngeal temperature) hypothermic CPB, where some infants lost CBF at flow rates as high as 25% to 35% of normal.¹³³ Thus, it is possible that the result of low-flow CPB in at least some infants is the opposite of what is intended in terms of using low-flow to avoid DHCA—that is, low-flow hypothermic CPB may result in, rather than prevent, cerebral ischemia. The development of critical closing and opening pressures during CPB may contribute to a no-reflow phenomenon and uneven brain cooling during low-flow CPB.⁵⁷ The notion of critical closing and opening pressures in the cerebral vascular bed (and other vascular beds as well) also suggests that blood flow may be more dependent on arterial pressure than pump flow rate in these circumstances and that a minimum mean arterial pressure is necessary to maintain adequate flow to the brain and other organs.

Hypothermic protection of the brain during periods of low or absent flow depends on homogeneous cooling of all brain regions. There is evidence that this may not occur, based on the temperature or oxygen saturation of jugular bulb venous blood, which indicates the likelihood of ongoing cerebral metabolic activity despite low tympanic or nasopharyngeal temperatures.^{42,57} These data indicate that tympanic or nasopharyngeal temperatures may not identify subsets of patients with inadequately cooled brains. Risk factors for nonhomogeneous and delayed brain cooling may include the position of the aortic cannula, vascular anomalies, and aortopulmonary and other collaterals, as well as blood gas or pH management strategy (see later), and the duration of cooling. For example, using alpha-stat pH management, the duration of core cooling prior to a period of DHCA was the intraoperative variable most closely associated with postoperative cognitive outcome. Over cooling times between 11 and 18 minutes, increasing cooling time by 5 minutes

increased the development score by 26 points. It was speculated that shorter cooling times (less than ≈ 15 minutes) permitted ongoing metabolism in nonhomogeneously cooled regions of the brain, making them susceptible to injury during the period of DHCA.¹³⁴ Also of interest, there was a trend for worse neurodevelopmental outcome (that did not reach statistical significance) with cooling times longer than 20 minutes, perhaps because of the effects of prolonging exposure to the deleterious consequences of CPB, including microembolic events.

Deep Hypothermic Circulatory Arrest

DHCA has been used since the 1970s for the repair of congenital heart defects, primarily in neonates and small infants, and occasionally in older children. Use of DHCA can decrease the length of time the patient is on CPB. This was an important advantage during the early congenital cardiac surgical experience, when limitations in CPB equipment and techniques put the neonate and small infant at increased risk. The impetus to minimize exposure to CPB has diminished as CPB methods for infants have improved. Continuous refinement of perfusion methods for neonates and infants has led to a reduction in DHCA use in many centers. Nonetheless, DHCA offers optimal surgical exposure in a small heart and chest by allowing removal of the perfusion cannulas, and its use (or similar alternatives, such as DHCA alternated with periods of intermittent perfusion) is unavoidable for some lesions.

Both surface and core cooling are used prior to DHCA. Surface cooling is facilitated during the induction of anesthesia and surgical exposure and cannulation for CPB by lowering the room temperature as low as possible (to $<20^{\circ}\text{C}$), placing ice-filled bags around the head and neck, and positioning the patient on a cooling/warming blanket set to approximately 10°C . Using these methods, the usual rectal temperature at the time of initiating CPB is approximately 33°C (temperature-related dysrhythmias and ventricular fibrillation are rare in neonates and small infants at core temperatures of greater than 28° to 30°C). For most cases of DHCA, an ascending aortic arterial cannula (the pulmonary artery is cannulated initially for hypoplastic left heart syndrome) and a single right atrial venous cannula are inserted. As noted, extremely rapid cooling (core temperature decreasing to 15° to 18°C in less than ≈ 15 minutes) is usually avoided. The efficiency of different heat exchangers can vary widely, in part because of their surface areas relative to membrane surface area and flow rates (see Table 108-1). Cooling is continued until both rectal and tympanic membrane temperatures are less than 18°C . Cardioplegia is administered, and CPB is then discontinued. Several pharmacologic adjuncts are usually given as part of DHCA. Many include an alpha blocker (such as phentolamine or phenoxybenzamine) in the pump prime to reduce vascular resistance, improve regional blood flow, and aid in homogeneous and effective cooling. High-dose methylprednisolone (30 mg/kg) is given for the reasons already discussed. Some administer sodium pentothal (5 to 10 mg/kg) just prior to the start of DHCA to reduce cerebral electrical activity and metabolism; this is based

in part on experience showing that up to 20% to 30% of neonatal brains will not be electrically silent despite tympanic and core temperatures of less than 18°C . As discussed previously, a higher hematocrit than used previously ($\approx 25\%$ to 28% instead of 15% to 20%) is now favored by many, on the basis of evidence that it does not impair the hypothermic cerebral circulation and may be associated with improved myocardial function, less total body water accumulation, and perhaps improved performance on some neurodevelopmental tests at 1 year of age.^{61,63} Finally, drainage of blood from the patient is promoted by several inflations of the lungs and manual compression of the abdomen. The venous cannula is then usually clamped and removed.

Before rewarming, initial steps are taken to remove air from the left ventricle, left atrium, and pulmonary veins. Cannulas are reinserted, and CPB is slowly resumed at 18°C .

There are different approaches to rewarming. In the oldest approach, rewarming begins immediately, maintaining a temperature differential between the warming circuit and patient's venous blood of less than 10°C and a maximum water temperature of 42°C . Because concerns about cerebral injury after DHCA and information about the potential protective effects of hypothermia and harmful effects of even mild hyperthermia after a cerebral injury have increased, many centers currently undertake a period (≈ 10 to 15 minutes) of 18°C perfusion on resumption of CPB after DHCA and try to limit both hyperthermic reperfusion (by keeping aortic perfusate temperatures lower) and post-CPB hyperthermia.^{20,57,135,136} Prior to aortic cross-clamp removal, mannitol (0.25 to 0.5 g/kg) is frequently given. Ionized calcium, which had been allowed to decrease to approximately 0.4 to 0.8 mmol/L during cooling and early rewarming, is normalized once the heart has had a period of reperfusion and the core temperature has increased to approximately 30° to 32°C . It is probably important to keep both flow rate and mean arterial pressure at age-appropriate normal values because of the loss of cerebral autoregulation and consequent pressure-flow dependence of CBF after DHCA. Once calcium is normalized and the patient is rewarmed to approximately 34°C , pulsatile ejection is stimulated by restricting venous return, and ventilation is begun; this is another opportunity to remove any residual intracardiac air. Observations of the heart, intracardiac filling pressures, arterial blood pressure, and other available information (e.g., contractility and filling on transesophageal echocardiography) are useful at this point to estimate the degree of inotropic support required when weaning from CPB. Typically, low doses of dopamine (≈ 5 to $7.5\text{ }\mu\text{g/kg/min}$) are all that is required.

Management of Arterial Blood Gases during Pediatric Cardiopulmonary Bypass

Most centers adjust oxygen delivery to the CPB circuit so that arterial PO_2 values are in the range of approximately 400 to 600 mm Hg. This hyperoxic approach is based on evidence that brain injury is greater during

normoxic CPB than with hyperoxic CPB.¹³⁷ Potential explanations for this effect include that the brain mainly uses dissolved oxygen during deep hypothermic CPB, the amount of gas microemboli is decreased when nitrogen is omitted from the sweep gas, and oxygen microemboli are resorbed much faster than those containing nitrogen.^{95,135} On the other hand, some centers favor significantly reducing PO₂ during CPB, to reduce oxygen radical production.^{25,137} This mechanism may be especially important in cyanotic infants, in whom antioxidant reserves and scavenging enzyme systems may be down-regulated.^{25,137,138} The issue remains unresolved, and it is likely that the relative benefits of the two oxygenation strategies depend in part on the organ system in question. For example, reperfusing myocardium (especially cyanotic myocardium) at lower PO₂ may be quite beneficial for recovery of cardiac function, whereas it has recently been stated that the significance of hyperoxia-induced oxygen radical injury to the brain is far less important than the deleterious effects of low perfusate PO₂, especially when CBF and cerebral autoregulation are impaired, as is the case with low-flow deep hypothermic (or circulatory arrest) CPB.¹³⁵

The optimal management strategy for pH and CO₂ during profound hypothermia, with or without DHCA, remains controversial. Both alpha-stat and pH-stat management strategies are used during pediatric CPB, and both have potential advantages and disadvantages. During hypothermia, the efficacy of the body's primary buffering systems (e.g., bicarbonate, phosphate) is markedly reduced, and amino acids become the most important intracellular buffers as temperature falls; of these, the α -imidazole ring of histidine is the most effective proton acceptor (i.e., buffer). Water is less ionized (into H⁺ and OH⁻) as temperature falls, and thus the pH of water (the major fluid in the body) increases with falling temperature. The neutral point of water (i.e., the pH at which [H⁺] = [OH⁻]) also rises as temperature falls. This state (the pH at which water is electrochemically neutral) is approximately pH 7.4 at 37° C and approximately pH 7.7 to 7.8 at profound hypothermic temperatures. Alpha-stat management is based on preserving electrical neutrality at reduced temperatures and therefore the buffering capability of the α -imidazole ring of the amino acid histidine. Most enzyme, receptor, and metabolic systems function best at pH 7.4; several have been shown to function more efficiently at 20° C and at a pH of approximately 7.7.^{139,140} Blood from a normal patient cooled under alpha-stat methods will have a pH of approximately 7.4 and a CO₂ concentration of approximately 40 mm Hg when the sample is warmed to 37° C in the blood-gas analyzer. The alleged biochemical advantages of preserving electrochemical neutrality and intracellular buffering via alpha-stat management include better preservation of metabolism and protein and enzyme function (by preserving intracellular pH [pH_i] and preventing abnormal charge accumulation on proteins) and slowing the diffusion of key charged intermediates such as ADP and adenosine monophosphate (AMP) out of the cell, thereby promoting faster recovery of oxidative metabolism and high-energy phosphates when oxygen and substrate supply are restored.¹⁴⁰ Alpha-stat management is

likely to be associated with better preservation of cerebral autoregulation at mild to moderate hypothermic temperatures, lower CBF, and less brain swelling. These features may have a net beneficial effect in adults, where microemboli and cerebral edema appear to be major components of the insult, as compared with the higher brain blood flow and greater microemboli load associated with pH-stat.^{107,141} On the other hand, the alpha-stat strategy causes a leftward shift in the oxyhemoglobin dissociation curve. In the setting of low flow, low perfusion pressures, and low temperatures, overall oxygen delivery under alpha-stat management may be marginal to meet metabolic needs, and CBF may be inadequate to evenly and effectively cool the brain.^{107,142,143}

In contrast, pH-stat uses a mathematical correction for the effects of temperature on pH and then adds CO₂ to the circuit to correct pH for the fall in temperature. pH-stat therefore attempts to normalize the patient's pH (i.e., make it ≈ 7.4) and PCO₂ at the hypothermic temperature. When this sample is analyzed at 37° C, it will be relatively acidotic (pH of ≈ 7.1 to 7.2) and hypercarbic (PCO₂ ≈ 60 to 70 mm Hg). The addition of CO₂ will theoretically lower pH_i and disrupt electrical neutrality. However, evidence suggests that pH-stat may only minimally reduce pH_i.^{144,145} The increase in CBF associated with pH-stat, along with the rightward shift in the oxyhemoglobin dissociation curve, may favor even and effective brain cooling and oxygen delivery as long as perfusion pressure and flow are maintained. Hypercapnia decreases cerebral metabolic rate, energy use, glycolytic flux, and lactate production.^{107,146-148} Hypercapnia and acidosis may also decrease excitatory amino acid neurotoxicity by inhibiting N-methyl-D-aspartate (NMDA) receptor function, glutamate release, and neuronal calcium fluxes.^{107,148,149}

Based on the work of Aoki and Swain showing that cerebral pH_i becomes alkalotic during deep hypothermia even with pH-stat management, it may be that the biochemical advantages of alpha-stat are largely present during pH-stat management and are supplemented by the effects of pH-stat to increase CBF and oxygen availability as a result of its effect to shift rightward the oxyhemoglobin dissociation.^{130,145,150} These effects are likely to be paramount in the neonate and infant exposed to low flow or no flow, because hypoxic and ischemic injury probably pose the greatest risk to the infant, in contrast to the adult with significant atherosclerosis and vascular disease managed at mild or moderate hypothermia, in whom minimizing microemboli and preserving autoregulation (and therefore favoring alpha-stat management) may be the primary pathophysiologic considerations.

A small retrospective study using relatively brief cooling times (<15 minutes on average) suggested that pH-stat might be preferable to alpha-stat in terms of neurodevelopmental outcome when DHCA is used for Senning correction of arterial transposition.¹⁵¹ In a larger, prospective, randomized, single-center study, no consistent improvement or impairment could be related to pH management strategy during deep hypothermic CPB.¹⁵² Overall, DHCA has been found to result in greater short-term (1 year) and long-term (8 years of age) functional neurologic and neurodevelopmental deficits compared

with low-flow CPB; interestingly, both strategies were associated with increased neurodevelopmental risk.¹⁵³ By contrast, in another study of patients with hypoplastic left heart after Norwood procedure, impaired neurodevelopmental outcome was not associated with the use of DHCA and also not associated with pH strategy or hematocrit.¹⁵⁴

On the basis of this information, many centers have begun to favor pH-stat management for infant and pediatric CPB when deep hypothermia, low flow, or circulatory arrest is going to be used.* Patient factors can also influence this choice. The presence of cyanosis and aortopulmonary collaterals are considered by many to be indications for pH-stat management; CO₂ increases pulmonary vascular resistance, leading to improved systemic blood flow in these patients; cerebral perfusion is directly increased by CO₂ and also by the reduction in flow through the collaterals.^{128,135,155}

Bleeding after Pediatric Cardiopulmonary Bypass

Bleeding is a significant problem after many cardiac surgical procedures in neonates, infants, and children. The cause in most cases is likely to be multifactorial. In addition to the difficulties surrounding heparinization and its antagonism by protamine (see Heparin Reversal, earlier), numerous factors (related to the patient, pathophysiology of the lesion, technical aspects of the operation, and the effects of CPB) can promote blood loss. Most of the procoagulant and anticoagulant blood factors are present in reduced concentration in neonates and infants; these concentrations approach adult values at varying rates over the first 6 to 12 months of life.^{79,80,82,157} Infants therefore appear to be functionally balanced albeit at a lower set-point, which enhances the effects of hemodilution by CPB. Reduced levels of both procoagulant and anticoagulant factors compared with age-matched controls have been found in many infants and children with congenital heart disease, particularly those with various forms of single-ventricle physiology.^{79,80,158} The cause is unclear at present, as is whether these abnormalities are linked to any functional disturbances (either increased or decreased) in ability to clot.

Increased bleeding can occur in association with lesions that increase systemic venous pressures (e.g., Fontan physiology, Mustard or Senning atrial baffles, right ventricular dysfunction) resulting from hepatic dysfunction, development of large venous collateral vessels, and high venous pressures. Hepatic dysfunction can also occur in lesions with significant systemic hypoperfusion (large left-to-right shunt, left-sided obstructive lesion such as critical coarctation). Cardiac lesions that generate large shear forces such as aortic stenosis and ventricular septal defects can promote the degradation of active von Willebrand factor multimers to less active and inactive monomers, leading to an acquired form of von Willebrand disease. Prostaglandin E1, used to maintain ductal patency preoperatively, can impair platelet function.

Changes attributed to cyanosis that increase the risk of bleeding may include reduced platelet function, increased fibrinolysis, decreased total body amount of clotting factors (resulting from polycythemia and hence decreased plasma volume), and the development of collateral vessels. Unlike most adult cardiac surgery, many congenital cardiac operations require extensive suture lines and reconstructions using tissue or prosthetic graft materials, often on high-pressure vessels (e.g., stage I operation for hypoplastic left heart syndrome, the arterial switch procedure). Reoperations also make up a substantial part of pediatric cardiac surgery.

The effects of CPB on blood activation, coagulation, and fibrinolysis are arguably greater in neonates and infants because of the greater degree of hemodilution, deeper degrees of hypothermia, higher shear forces resulting from higher flow rates, more blood trauma and greater blood-air contact (higher flows, small tubing and cannulas, more cardiomyotomy suction), and proportionately greater degree of blood contact with the foreign surface. CPB reduces platelet number and causes platelet dysfunction by several mechanisms, including hypothermia, contact activation from the CPB circuit, activation via coagulation mechanisms, and cleavage of platelet adhesive receptors by fibrinolytic proteases that are also activated by CPB. Platelet number in neonates and small infants is approximately halved at the end of bypass following protamine reversal, and platelet function is believed to be markedly impaired for the reasons outlined. Ongoing consumption of platelets and clotting factors resulting from bleeding at complex and pressurized anastomotic sites can add to the problem.

Neonates presenting for CPB are likely to have normal platelet counts but reduced (compared with age-matched subjects, who, as already noted, have lower clotting factor levels compared with adult values) concentrations of factors II, VII, VIII, IX, and X. A subset of neonates may also have significantly lower fibrinogen at the outset, which can then be critically low at the end of bypass and be a major contributor to post-bypass bleeding.¹⁵⁷ Other significant abnormalities at the end of CPB after protamine administration include further reductions and functionally low concentrations of factors V, VII, and VIII. Low post-protamine platelet counts and fibrinogen concentrations correlate with bleeding in neonates and small infants.¹⁵⁹

Treatment of Bleeding after Cardiopulmonary Bypass

The treatment approach to post-CPB bleeding in pediatric patients is based on the preceding considerations, driven by both the expected coagulation abnormalities and the presence of complex reconstructions and extensive vascular suture lines. Platelets are the initial therapy after adequate heparin reversal because of the documented deficiencies in platelet count and function. One to two units of platelets are typically administered to neonates and small infants to start, and up to six to eight units are administered in larger children. One rule of thumb has it that each unit per 10 kg body weight will increase platelet count by approximately 50,000/mm³;

*References 20, 61, 143, 151, 155, and 156.

the actual result in this setting is less, at least in part because administration is done during ongoing bleeding and consumption. Also, platelets are supplied in fluid that is essentially plasma, so a fair amount of clotting factors is supplied simultaneously. Cryoprecipitate is usually the next blood component administered after platelets, and it is chosen in part because it is a good source of fibrinogen in a relatively small volume. This sequence of platelets followed by cryoprecipitate has been shown to restore hemostasis in most pediatric patients after CPB.¹⁵⁹ Fresh-frozen plasma is usually reserved to replete measured factor deficiencies not amenable to cryoprecipitate, particularly because there is some evidence that it has little effect or may even be detrimental to most post-CPB infants.¹⁵⁹ Some pediatric cardiac centers prefer to use fresh whole blood as the primary therapy after protamine reversal. When used within 24 to 48 hours of collection, fresh whole blood contains active platelets and significant amounts of clotting factors, and it has been shown to reduce bleeding, transfusion requirements, and the use of other components in both neonates and adults.^{160,161} One major limitation is the difficulty in obtaining reliable quantities within the 48-hour time frame, in part because of required blood banking procedures and testing for infectious agents. Thromboelastography may help identify coagulopathy and may help direct the treatment of bleeding after CPB, thereby reducing blood product utilization.^{162,163}

Although truly accelerated fibrinolysis is probably uncommon during pediatric CPB (and largely resolves after protamine administration),^{73,159} it is likely that the activation of the fibrinolytic system that accompanies surgical trauma and bleeding, and particularly in association with CPB-induced activation of coagulation and inflammatory cascades, has a significant role in consumption of clotting factors, generation of anticoagulant degradation products, and loss of adhesive receptors on platelets. For these reasons, antifibrinolytic agents such as ϵ -aminocaproic acid and tranexamic acid have become increasingly popular. Until recently, in many pediatric centers, aprotinin was also used frequently for neonates and for complex repairs. It is not available for clinical use at present because of reports of increased complications in adult cardiac surgery patients; these include stroke, renal failure, graft occlusion, and perhaps death. Interestingly, meta-analyses of adult aprotinin studies indicate a protective effect against neurologic injury, particularly stroke, that appeared to be at least in part the result of reduced patient reinfusion of shed blood.^{164,165} Of course, the applicability of the adverse events and likely underlying mechanisms in adult patients to the pediatric population is highly questionable.^{166,167} At present, there is little controlled evidence that antifibrinolytic agents are beneficial in terms of, for example, blood loss, transfusion requirement, and platelet dysfunction, in primary operations, although many centers use them for procedures such as arterial switch operations and stage I hypoplastic left heart reconstruction. A meta-analysis of randomized trials using tranexamic acid concluded that the evidence in support of its use is weak.¹⁶⁸ There is evidence in favor of their use for reoperations, particularly of the complex variety.¹⁶⁹⁻¹⁷³ Theoretical concerns remain about potential

deleterious prothrombotic consequences during low flow or DHCA and in tenuous anatomic or circulatory situations postoperatively (e.g., Fontan fenestration, coronary anastomoses, surgical shunts), although there are no direct reports of such and one retrospective study was unable to identify any role for these agents in similar problems.^{169,174}

For problematic and excessive bleeding resistant to blood product treatment, administration of activated recombinant factor VII has been described as being effective.¹⁷⁵⁻¹⁷⁷ There are concerns of the potential risk of thrombotic complications associated with factor VIIa administration. This has not been demonstrated in accumulated series.¹⁷⁷

Organ Injury during Pediatric Cardiopulmonary Bypass

The damaging mechanisms of CPB include global (i.e., low-flow or DHCA) and regional (e.g., heart, lung, gastrointestinal tract) periods of ischemia and reperfusion, activation of multiple limbs of the systemic inflammatory response, and intramyocardial and systemic air and particulate microemboli. During hypothermic CPB at full flow rates, the skeletal muscle functions as a large-capacitance reservoir, and blood flow is to some extent shunted away from the vital organs. During low-flow hypothermic CPB, skeletal muscle vasculature constricts and the flow to vital organs is preserved, so oxygen delivery is able to maintain oxygen consumption despite approximately a 50% reduction in flow rate.¹⁷⁸ The presence of large collateral vessels, arterial obstructive lesions, cannula position, and other shunts from the systemic circulation may further compromise vital organ blood flow, as previously discussed.

Pulmonary Effects

The lungs are at significant risk for injury from CPB. This is likely to be caused by hemodilution, inflammation, and ischemia-reperfusion effects.^{179,180} Infants with current (e.g., infection, congestive heart failure, pulmonary overcirculation) or prior (e.g., respiratory distress syndrome, bronchopulmonary dysplasia) disorders may be at greater risk. Manifestations of CPB-induced lung injury include loss of endothelium-dependent dilation and increased pulmonary vascular resistance, decreased compliance, decreased functional residual capacity, increased alveolar-arterial oxygen difference, leakage of fluid into the interstitial space, and reduced surfactant activity.¹⁸⁰⁻¹⁸⁶ Hemodilution promotes fluid extravasation by reducing oncotic pressure. Activated complement, leukocytes, cytokines, and leukotrienes induce alveolar and capillary membrane damage; augment capillary leak; increase platelet and white blood cell plugging; and induce the release of additional mediators that further increase pulmonary vascular resistance and pulmonary parenchymal and vascular damage. Facilitating lung cooling by allowing a period of pulmonary blood flow on CPB during core cooling has been suggested as one means to reduce ischemic lung injury and its consequences.¹⁸⁷

Renal Effects

As many as 3% to 7% of children have evidence of renal dysfunction after CPB.¹⁸⁸ However, estimates vary depending on the criteria used: 11% using AKIN (Acute Kidney Injury Network) criteria or 51% when using RIFLE (*risk, injury, failure, loss, and end-stage kidney disease*) criteria.^{189,190} Most of the acute kidney injury defined this way will resolve in 48 to 72 hours, and mild renal dysfunction may not have any bearing on postoperative outcomes.^{189,190} The risk of acute kidney injury in neonates may be as high as 64%.¹⁹¹ Preoperative renal dysfunction or injury and low cardiac output after CPB may be the best predictors of post-CPB renal dysfunction. Glomerular filtration rate and renal diluting and concentrating abilities are immature in neonates and very young infants. Preoperative renal injury appears to be more likely in neonates, who may in fact have multiorgan dysfunction after delivery and initial stabilization (e.g., hypoplastic left heart syndrome, arterial transposition), as well as in older patients with long-standing systemic ventricular dysfunction, chronically elevated systemic venous pressures, or cyanosis (e.g., “failing” Fontan circulations, tetralogy of Fallot with severe right or biventricular dysfunction).¹⁹² Low flow and reduced mean arterial pressure, nonpulsatile perfusion, and hypothermia lead to the production and release of hormones such as endothelin, catecholamines, antidiuretic hormone, atrial natriuretic factor, and renin/angiotensin.^{101,180,188,193} In addition to renal dysfunction, these factors may contribute to increased total body water, delayed fluid clearance after CPB, and related complications such as myocardial and pulmonary interstitial edema, delayed chest closure, and prolonged ventilatory support. Few studies have been specifically devoted to infant and pediatric heart disease patients in terms of renal protection or preventive therapies. In larger patients, vacuum-assisted venous drainage has some theoretical advantages. Several recent adult cardiac surgery studies (where, of course, much of the underlying pathophysiology may be different) suggest that relatively low doses of fenoldopam or nesiritide can reduce renal-related morbidity in at-risk patients.¹⁹⁴⁻¹⁹⁸

Brain Injury

Neurologic injury continues to be one of the most problematic aspects of surgery for congenital heart disease. As overall operative mortality has declined in association with improved cardiac outcomes and life expectancy, quality-of-life issues have assumed greater importance. Prevention of neurologic injury has therefore become increasingly important. Earlier retrospective series estimated the incidence of major neurologic injuries after pediatric heart surgery to be between approximately 2% and 30%.^{57,199,200} Although there appears to have been a progressive decline in major complications such as seizures, persistent choreoathetosis, and severe developmental delay (for reasons that are largely unknown), more subtle but significant cognitive and neurodevelopmental delays in IQ, language and motor skills, attention, learning skills, visual and spatial skills, and working memory have recently been found in children who underwent

neonatal repair of arterial transposition, as well as in some single-ventricle patients and those who underwent complicated biventricular repairs; outcomes were generally worse in those who underwent DHCA.^{153,201-203} Cognitive development also appears to be lower in school-age survivors of hypoplastic left heart syndrome and patients with Fontan physiology.^{204,205} Risks for lower achievement included hypoplastic left heart syndrome, use of DHCA, and reoperation within 30 days; brain magnetic resonance imaging (MRI) has been used with increasing frequency to detect abnormalities before and after infant cardiac surgery and other procedures.²⁰⁶⁻²¹² Interestingly, it appears that a substantial number of infants with congenital heart disease can manifest a variety of brain MRI abnormalities before surgery as well as after interventional cardiac procedures (e.g., balloon atrial septostomy). New MRI abnormalities have been observed at equal rates in children undergoing cardiac surgery with and without CPB, although, when CPB was used, the duration of bypass was associated with increased severity of the new abnormalities; DHCA was associated with the severity of new MRI findings in infants undergoing arch surgery; and the severity of new postoperative MRI abnormalities was associated with brain maturity score and their presence before surgery.²¹³

It has become apparent that preoperative, intraoperative, and postoperative factors are involved.²¹⁴ The developing infant brain may be particularly susceptible to injury by hypoxia, ischemia-reperfusion, and the systemic inflammatory response because of its relatively fragile vasculature, high metabolic activity, and the fact that it is undergoing an intensive period of neuronal migration, axonal outgrowth, target finding and arborization, synaptogenesis, myelination, astroglial development, and selective neuronal reduction (largely via apoptosis).¹⁰⁷ Most if not all of these processes are under the control of biochemical factors, neurotransmitters, and gene expression pathways that are likely to be affected by CPB and its consequences (e.g., cytokine and growth factor production, generation of oxygen radical and nitroxyl radical species, and altered release and reuptake of excitotoxic amino acid neurotransmitters caused by ischemia).

A substantial number of children with congenital heart disease have genetic syndromes associated with developmental delay of various sorts, including Down syndrome and the CATCH-22 syndrome.²¹⁵ The latter is linked to microdeletions in the 22q11 region of chromosome 22, DiGeorge and velocardiofacial syndromes, developmental delays in language and speech, and mild hypotonia, and it is present in 2% to 10% of children with congenital heart disease. It seems likely that other genetic abnormalities as yet undefined result in both neurologic problems and congenital heart disease. Indeed, a sizable number of children with heart disease may have congenital brain malformations; more than 30% of infants with hypoplastic left heart syndrome have evidence of brain dysgenesis or other anomalies before surgery.^{98,216,217} Low cardiac output, high venous pressures, thromboemboli, and chronic cyanosis are all likely to contribute to both gross and subtle neurocognitive lesions.^{135,216,218}

Intraoperative causes of brain injury include abnormalities of cerebral autoregulation and cerebral perfusion,

ischemia-reperfusion mechanisms, and emboli. Many of these factors were discussed previously. The “safe” period of DHCA remains controversial, and in part it depends on how it is defined and under what conditions of flow, pH, temperature, cooling strategy, and patient population it is assessed. Using experimental energetic depletion or the cerebral metabolic rate for oxygen as the endpoint led to estimates of 20 to 30 minutes or 40 to 65 minutes, respectively.^{69,130} Clinical experience and some evidence suggest periods of DHCA as short as 20 minutes or as long as 45 minutes before major complications such as seizures or choreoathetosis begin to increase in frequency.¹⁰⁷ Overall, the consensus has become that the risk of neurologic injury and developmental abnormalities increase and IQ decreases in direct proportion to the duration of DHCA.^{143,153,202,203,219-222}

This realization has led to evaluation of methods to avoid DHCA or reduce its duration, with the understanding that in some anatomic circumstances it cannot be avoided. The problems and potential for neurologic dysfunction with low-flow hypothermic bypass were discussed previously, and recent clinical outcome evidence supports the notion that this strategy is far from a perfect solution, although it is better than DHCA.^{57,132,133,153,201} Use of selective cerebral perfusion to avoid or reduce the use of DHCA appears to be an attractive and increasingly popular option. In many centers, the flow rates and perfusion pressures used during selective cerebral or arch perfusion are guided by continuous measurement of CBF velocity or NIRS.²²³⁻²²⁹ It is important to note, however, that these techniques have yet to be subjected to widespread and thorough appraisals or to controlled comparisons with DHCA or other low-flow techniques.⁶¹

The post-bypass period is also receiving increased attention as a vulnerable period for neurologic injury. As discussed, both low-flow deep hypothermic CPB and DHCA techniques can lead to compromises in CBF, autoregulation, and metabolism. Therefore, ensuring appropriate cardiac output, cerebral perfusion pressure, and oxygen delivery (i.e., appropriate hematocrit for the level of oxygen saturation and cardiac output) in the post-operative period are probably quite important. In addition to standard volume replacement and inotropic maneuvers, more novel strategies to support cardiac output in this setting include delayed sternal closure and ready use of extracorporeal membrane oxygenation.^{20,230,231} Maintaining normothermic or even mildly hypothermic body temperatures in the first 24 to 48 hours postoperatively may also be beneficial.¹³⁶

Clearly, the ability to sensitively and accurately assess and follow the status of the brain, as well as to guide and evaluate therapeutic interventions, would be advantageous. Although various forms of perioperative neurologic monitoring (e.g., electroencephalography, NIRS, cerebral Doppler blood flow velocity) are used and advocated with increasing frequency, no one technique or combination of techniques has emerged to fill this need.^{229,232-236} Most centers currently use some form of NIRS monitoring of cerebral (and often somatic as well) oxygen saturation. The NIRS value reflects tissue (arterioles, venules, capillaries) oxygen saturation, and is (in a somewhat oversimplified fashion) algorithmically

weighted to represent approximately 85% venous blood and 15% arterial blood. When used in the cerebral position, the NIRS value reflects frontal cortex oxygen content; the measured values most closely correlate with, in most patients, jugular bulb/jugular venous or SVC oxygen saturation; thus, in some ways, it can function as a noninvasive monitor of “mixed” venous O₂ saturations. There is some experimental data indicating that both the degree and the duration of cerebral “desaturation” may predict neurologic injury.²³⁷⁻²³⁹ However, human clinical data demonstrating a correlation between NIRS and neurologic injury or outcome are minimal, and data defining when intervention based on NIRS (i.e., level of desaturation) might be indicated. How to best intervene and whether NIRS-driven interventions alter outcome remain to be generated.²³⁹⁻²⁴¹ There may also be a role for improved techniques to detect microemboli during CPB.²⁴²⁻²⁴⁴

Stress Response to Cardiopulmonary Bypass

The stress response to CPB is characterized by the release of a large number and diverse group of neurohumoral substances, including catecholamines, endothelin, various prostaglandins, cortisol, and growth hormone. The concentrations that have been measured in neonates and infants during or soon after CPB are some of the highest measured in humans, and they generally exceed those measured in adult CPB patients by 5-fold to 10-fold.^{101,245} Stimuli include extensive and prolonged foreign surface contact, profound hypothermia, low flow, low perfusion pressure, and nonpulsatile perfusion. Clearance of many of these compounds by the liver, kidney, or lungs may also be delayed. Possible deleterious consequences include vasoconstriction and reduced organ perfusion, direct tissue injury, pulmonary hypertension, endothelial damage, and increased pulmonary vasoreactivity.

On the other hand, the release of many of these compounds and the response overall clearly has adaptive benefits. However, it is unclear what level, circumstances, or substances cause a net harmful response, to what extent acutely ill infants with congenital heart disease require some degree of stress response for hemodynamic stability, wound repair, and overall homeostasis, and to what degree the seemingly exaggerated response seen particularly in neonates and infants exposed to CPB is pathologic and should be attenuated. Decreased stress response hormones and possibly improved morbidity and mortality have been associated with high-dose synthetic opioid administration to infants undergoing CPB and other stressful procedures.^{245,246}

Systemic Inflammatory Response to Cardiopulmonary Bypass

CPB causes a systemic inflammatory response via multiple mechanisms. These mechanisms include surgical trauma, blood contact with the CPB circuit, ischemia-reperfusion injury, and protamine administration.^{179,247-254} These initiating events stimulate complex and interconnected cell- and humoral-based systems that include activation of the complement, coagulation, and fibrinolytic pathways, endotoxin release, cytokine production,

endothelial activation and expression of leukocyte adhesion molecules, leukocyte and platelet activation, and production and release of oxygen radicals, nitric oxide, prostanoids, eicosanoids, and proteolytic enzymes (e.g., myeloperoxidase and superoxide from activated neutrophils). The resultant tissue and organ injury, capillary leak, increased need for inotropic and ventilatory support, and perhaps effects on infection risk are widely believed to have a major impact on duration of hospitalization and overall outcome.²⁵⁵

Complement activation occurs via both alternate (stimulated by foreign surface contact, endotoxin, and kallikrein) and classical (protamine) pathways. Significant increases in activated complement fragments occur with initiation of bypass, and further still during rewarming, and these levels have correlated with post-CPB renal, cardiac, and pulmonary dysfunction.^{179,180,247,249,256} Various complement fragments cause white cell and platelet activation, white cell free-radical production and degranulation, smooth muscle constriction, and capillary leak. Terminal complement fragments and the membrane attack complex can cause direct cell lysis.

Blood concentrations of bacterial endotoxin can increase because of its almost ubiquitous presence in sterile fluids and equipment and also perhaps because of decreased intestinal perfusion, which can augment reperfusion injury independent of endotoxin.^{257,258} Endotoxin can directly injure endothelial cells and cause capillary leak, and it can stimulate the production of proinflammatory cytokines such as tumor necrosis factor (TNF), interleukin (IL)-1, IL-6, and IL-8. Cytokine production can also be stimulated by foreign surface contact, complement fragments, and other cytokines. Mechanisms of cytokine-induced tissue injury are multiple.

Cytokines such as IL-1 and TNF are directly toxic to endothelial and other cells, cause wasting and edema, cause myocardial contractile dysfunction, and stimulate a number of cytotoxic and cytoprotective signaling mechanisms such as inducible (high-output and potentially cytotoxic) nitric oxide production, various proapoptotic and antiapoptotic pathways and proteins, enhanced oxygen radical injury, and induction of cellular antioxidant enzymes. Levels of TNF and IL-1 are inconsistently increased by CPB in neonates and infants. Cytokine-induced nitric oxide production can result in profound hypotension (it is the major mechanism of vascular depression in septic shock), myocardial depression, and inhibition of cellular respiration and metabolism. IL-6 has been demonstrated in some studies to be a good predictor of clinical outcome and may be related to the extent of tissue injury.¹⁸⁰ IL-8 is a potent neutrophil chemoattractant and also causes leukocytosis and activation of neutrophil proteases and free radical enzymes. Increased IL-8 has been found in pediatric CPB in proportion to ischemic and total bypass times.^{180,183,248,259} Some children have increased levels of some cytokines preoperatively; the causes and significance of this finding are unclear, but there is some evidence that neonates with a preoperative biochemical profile consistent with inflammation (e.g., increased plasma elastase and complement fragments) are more likely to manifest a capillary leak syndrome postoperatively.^{248,255}

Neutrophil activation is believed to be an important mechanism of cellular injury during and after CPB. It is produced by a wide variety of stimuli, including foreign surface contact, endotoxin, cytokines, complement, platelet-activating factor, and ischemia-reperfusion. Activated neutrophils express proadhesive molecules on their cell surface (that are complementary to ones induced on endothelial and other cell membranes), marginate into the tissue, and have increased lipoxygenase and myeloperoxidase activities (the source of superoxide and hypochlorous acid, respectively) and release neutrophil elastase. These products cause damage to lipids, proteins, and DNA. Elastase also causes endothelial damage, inactivates serine proteases in the coagulation pathway, and cleaves adhesive receptors from the platelet membrane.^{107,260-262} Both myeloperoxidase and elastase, as well as evidence of neutrophil-mediated oxidant injury, have been detected after pediatric CPB.^{25,180,263}

It has recently become apparent that CPB also induces a corresponding increase in anti-inflammatory cytokines such as IL-10 and IL-1 receptor antagonist (IL-1ra). C-reactive protein (CRP), an acute phase protein that is a marker of inflammation and has anti-inflammatory effects by decreasing neutrophil chemotaxis, also increases during and after pediatric CPB.[†] Transient immunosuppression mediated by these events and others such as loss of activated neutrophils and inhibition of cellular immune responses have also been found after pediatric CPB.²⁶⁴

Overall, there is substantial variability in the release pattern and plasma concentrations of cytokines in infants and children undergoing cardiac surgery compared with adults.^{183,248,254,265-267} Although increased elements of the systemic inflammatory response are generally associated with increased risk of postoperative organ dysfunction and morbidity and mortality, better-designed studies with direct assays and endpoints are necessary to truly define any cause-effect relationship between systemic inflammatory response mediators and organ damage. It is also likely that the *balance* between proinflammatory and anti-inflammatory stimuli and their diverse effects on a wide range of cellular types and functions must be taken into account.^{254,268} Finally, the possibility that at least some of these substances are required to regulate the overall response and in fact potentially contribute to eventual repair and resolution should not be forgotten. For example, although the deleterious effects of substances such as TNF- α and cyclooxygenase pathway derivatives have been demonstrated in numerous cellular and animal models, genetic or pharmacologic abrogation of these pathways can also lead to increased cell death and organ dysfunction under clinically relevant circumstances (e.g., ischemia-reperfusion).

Other Current Approaches to Limiting the Negative Consequences of Pediatric Cardiopulmonary Bypass

Efforts and potential targets to decrease the negative impact of CPB in infants and children that have been

[†]References 179, 180, 248, 252, 254, and 264.

discussed include modifications to reduce circuit area and volume, improve venous drainage, and define the optimal pH, hematocrit, temperature,²⁶⁹ flow rate, arterial pressure, and duration of CPB and DHCA. Additional targets of intervention have included oxygen, anesthetic technique, remote ischemic preconditioning, and peritoneal dialysis.²⁷⁰⁻²⁷³

Steroids

Administration of relatively high doses of steroids prior to pediatric CPB (either dexamethasone or methylprednisolone) may suppress the production of proinflammatory cytokines and improve organ function.^{223,274-276} Because a major effect of steroid treatment is to alter gene expression and cellular activation, maximal effect may require administration some time before bypass (up to 8 hours) and repeated dosing.²⁰ Improvements in body water accumulation, alveolar-arterial oxygen gradients, pulmonary artery pressure, duration of mechanical ventilation, and length of intensive care unit stay have been observed.^{20,274,275} Results from more extensive investigations in adults confirm beneficial alterations in the balance of proinflammatory to anti-inflammatory mediators.²⁷⁷ However, there were no significant effects on fluid balance, and there were possibly detrimental effects on pulmonary function and glucose homeostasis (hyperglycemia). Furthermore, as with the stress response, it remains unclear whether broad-spectrum suppression of the systemic inflammatory response is beneficial. These differences may be partly because steroids may be more likely to show a positive effect in neonates and infants in whom the magnitude and consequences appear to be greater. However, there is some evidence that at least more prolonged periods of corticosteroid administration may be detrimental to the developing brain. Steroids are being used not only preoperatively and intraoperatively but also postoperatively for the treatment of hemodynamic instability and around the time to extubation. Prolonged steroid exposure may suppress the adrenal gland and use may also predispose to infection. In retrospective studies, data are conflicting as to the benefit of steroids.²⁷⁸⁻²⁸¹ Thus, it would seem that caution is warranted until large randomized, prospective, placebo-controlled studies with tightly regulated perioperative management are performed in pediatric patients.

Ultrafiltration

Conventional and modified ultrafiltration techniques are being used with increasing frequency during pediatric cardiac surgery. Potential beneficial mechanisms include hemoconcentration, removal of various inflammatory mediators and vasoactive compounds in the ultrafiltrate, and decreased total body water and tissue edema. Significant clinical improvements in tissue edema, post-CPB weight gain, hematocrit, blood pressure, global left ventricular function, lung compliance, oxygenation, and duration of mechanical ventilation have been reported, along with decreased postoperative bleeding, decreased postoperative transfusion and blood product requirements, and decreased pulmonary vascular resistance; one

or more of these benefits have been observed in many, but not all, studies.^{252,259,282-289} Less clear are the mechanisms responsible for these effects, because significant reductions in blood concentrations of inflammatory cytokines, complement fragments, and prostanooids have not been universally identified.^{252,282,290} Although ultrafiltration techniques appear to be safe for infants and children, there is theoretically valid concern about removal of protective mediators and deleterious increases in viscosity and clotting factors (i.e., hypercoagulability). A recent meta-analysis of randomized trials found that modified ultrafiltration led to higher hematocrit and higher mean arterial pressure compared with conventional ultrafiltration.²⁹¹ Future studies are needed to define the mechanisms of the ultrafiltration effect and identify patients who are most likely to benefit.

SURGICAL APPROACHES, CARDIOPULMONARY BYPASS, AND MECHANICAL CIRCULATORY SUPPORT IN CHILDREN

Francis Fynn-Thompson • Ravi R. Thiagarajan • Luis Quinonez

CHAPTER OUTLINE

EXTRACORPOREAL MEMBRANE OXYGENATION

Overview of Uses

Indications

- Preoperative Resuscitation
- Inability to Wean from Cardiopulmonary Bypass
- After Cardiotomy
- Cardiomyopathy, Myocarditis, and Bridge to Transplantation
- After In-Hospital Cardiac Arrest and CPR

TECHNICAL ASPECTS OF ECMO CANNULATION

Access

Special Circumstances

- Single Ventricle
- Femoral Cannulation
- Neck Cannulation
- Venting

Conduct of Cannulation

Circuit and Cannula Management

Weaning from Extracorporeal Membrane Oxygenation

INTRA-AORTIC BALLOON COUNTERPULSATION

VENTRICULAR ASSIST DEVICES

Nonpulsatile Devices

Pulsatile Devices

Berlin Heart

EXPANDING VAD SUPPORT TO CHALLENGING PEDIATRIC POPULATIONS

Single-Ventricle Anatomy and Ventricular Assist Device Support

Posttransplant Graft Failure and Ventricular Assist Device Support

Destination Ventricular Assist Device Therapy in Children

LONGER-TERM OUTCOMES FROM MECHANICAL SUPPORT IN CHILDREN

For infants and children, mechanical support of the circulation has important roles in providing short-term circulatory support for reversible myocardial failure, in providing cardiopulmonary support before and after cardiac surgery, and in providing longer-term support as a potential bridge to cardiac transplantation. Mechanical circulatory support (MCS) modalities commonly available include extracorporeal membrane oxygenation (ECMO), intra-aortic balloon pump (IABP) counterpulsation, and ventricular assist devices (VADs). Although a variety of assist devices are available for adult-size patients, the need for miniaturization has delayed their application in children. ECMO therefore remains the most common form of MCS for pediatric patients. ECMO was first introduced to provide respiratory support in pediatric patients with severe lung

disease failing mechanical ventilator support. Some institutions with an established ECMO program have been able to transition this methodology to provide biventricular support and oxygenation in pediatric patients with a failing circulation.¹⁻³ There are no established guidelines for the indications or management of cardiac ECMO support, and there is considerable inter-institutional variability with respect to use and outcomes, based on local experience and philosophy. VADs offer the potential for both short- and long-term support of circulation in patients who do not have concurrent pulmonary parenchymal or vascular disease, and there is increasing experience in developing this form of support as an effective longer-term bridge to transplantation in the pediatric patients with heart disease.

EXTRACORPOREAL MEMBRANE OXYGENATION

Overview of Uses

The use of ECMO to support children with impaired gas exchange failing to respond to mechanical ventilation as a result of acute respiratory disease is now an accepted and successful therapy. This is particularly true in neonates with a variety of parenchymal and vascular lung diseases (e.g., meconium aspiration, respiratory distress syndrome, diaphragmatic hernia, persistent hypertension of the newborn) survival outcomes are excellent with the use of ECMO.^{3,4} Good ECMO outcomes in these patients depends on the early diagnosis of severe pulmonary failure, the prompt institution of ECMO, and the reversible nature of the pulmonary dysfunction.⁴ However, the advent of other therapies, such as high-frequency oscillatory ventilation, surfactant therapy, permissive hypercapnia, and inhaled nitric oxide, has led to a reduction in the need for ECMO in neonates.⁵⁻⁷ According to the cumulative data on 55,658 patients reported by the Extracorporeal Life Support Organization (ELSO) Registry, 75% of all neonates who have been placed on ECMO for respiratory support have survived to discharge from hospital (Table 109-1).⁵ The outcome for older patients with

respiratory failure is considerably lower, with the reported cumulative survival for pediatric and adult patients placed on ECMO for respiratory support being approximately 57% and 56%, respectively.

The past decade has seen a steady increase in the number of patients and institutions using ECMO to support a failing circulation, both after congenital cardiac surgery or as a bridge to transplantation.^{5,8-19} Another growing indication for ECMO is its use during resuscitation from cardiac arrest. ECMO can be deployed rapidly during cardiac arrest in patients failing to respond to conventional cardiopulmonary resuscitation; however, ECMO use and efficacy in promoting survival when used for this indication is controversial.^{8,10,11,20-22}

Despite the increased enthusiasm for ECMO support of the circulation, the survival to discharge as reported by the ELSO registry (40% for neonates and 49% for pediatric patients) has not changed much over the past decade (Fig. 109-1) and has lagged considerably when compared with the experience with respiratory ECMO (Table 109-2).⁵ The majority of cardiac patients are given ECMO after cardiac surgery. Adverse outcomes after cardiac ECMO are primarily related to irreversible underlying cardiac disease and to the presence of significant end-organ injury before ECMO deployment. Recovery from severe myocardial dysfunction while on mechanical support can occur, provided the myocardium has only sustained a transient and reversible injury. ECMO facilitates ventricular recovery by reducing myocardial wall tension, increasing coronary perfusion

TABLE 109-1 Survival after ECMO Support

Age Group and Indication	No. of Patients	No. That Survived to Discharge
Neonates

pressure, and maintaining systemic perfusion with oxygenated blood.

In infants, in whom myocardial failure is frequently biventricular and associated with respiratory insufficiency or pulmonary hypertension, ECMO is the preferred means of mechanical support. Although there has been some support for the concept of “resting the lungs” for patients who are given ECMO for respiratory failure and lung injury,⁴ in cardiac patients in who ejection is present, coronary blood flow is often from left ventricular ejection. Mechanical ventilation with increased fraction of inspired oxygen concentration in inspired air can increase oxygen content of blood returned to the left heart and thus can improve myocardial oxygen delivery and may promote recovery. The heart must regain contractile function and conduction as soon as possible to maintain a workload and to avoid involution of the myocardial mass. This requires frequent evaluation, often with echocardiography, and it is critical that overdistention of the heart be avoided.

It also is important to appreciate the differences between the ECMO circuit and management, and the routine cardiopulmonary bypass (CPB) used during cardiac surgery. The ECMO circuit is a closed circuit. It has limited ability to handle any air in the venous limb of the circuit, and careful de-airing of both the arterial and venous cannulas is essential when connecting to the ECMO circuit. The average duration for cardiac ECMO runs reported to ELSO over the past 15 years has increased slightly from approximately 4 to 5 days to about 5 to 7 days; the longest reported run is 62 days.⁵ These data emphasize that ECMO should be viewed only as a relatively short-term support of the circulation; beyond 7 days of ECMO support, the chances of successful decannulation and survival decrease substantially. These data also support the need to develop longer-term mechanical support devices, particularly as a bridge to transplantation for patients on ECMO who remain suitable candidates for cardiac transplantation.

The significant time limitation associated with cardiac ECMO use indicates that, ideally, only patients with known reversible cardiac disease should be considered candidates for cardiac ECMO. However, this is often not possible when a quick decision needs to be made to place a patient on ECMO because of cardiac arrest or a severe low cardiac output state. In general, institutions with an efficient and well-established ECMO service are more likely to use this form of support for the failing circulation. However, differences in decision making regarding ECMO candidacy and timing of ECMO deployment, case type and surgical complexity, surgical technique and CPB management used, and many other confounding factors make comparison of efficacy of ECMO among institutions difficult.²³ However, one can make a case that ECMO should be readily available in any center undertaking complex congenital cardiac surgery, as it can provide effective short-term cardiac support while awaiting myocardial recovery in some patients improving their probability of survival. Establishing a structured and coordinated team approach to cannulation is a key step for any successful ECMO service.¹¹ In our experience at Boston Children’s Hospital, the introduction

of a dedicated cardiac ECMO program and development of a rapid response system for its use during active resuscitation has contributed to an increase in the survival-to-discharge rate for ECMO circulatory support, from 45% in 1995 to 59% in 2002, regardless of the diagnosis or indication for cardiac support.²¹

Indications

There is no specific cardiac procedure or diagnostic group for which ECMO is a proven therapy. Rather than trying to determine indications for cardiac ECMO according to specific diagnoses or procedures, the indications can be examined in five broad categories: preoperative resuscitation; inability to wean from cardiopulmonary bypass; postcardiotomy; cardiomyopathy, myocarditis, and bridge to transplantation; and after in-hospital cardiac arrest and cardiopulmonary resuscitation (CPR). According to the ELSO Registry report of outcomes based on broad diagnostic categories, patients given ECMO because of complications related to fulminant myocarditis have the highest survival rate (Table 109-3), although it lags behind the successful outcomes achieved with ECMO for respiratory support in neonates. The survival from cardiac ECMO to hospital discharge according to selected congenital defects is shown in Table 109-4.

From Extracorporeal Life Support Organization: International Summary, July 2013.

Preoperative Resuscitation

ECMO can be beneficial for critically ill patients awaiting cardiac surgery, enabling preoperative stabilization and optimization or prevention of end-organ dysfunction before repair. These patients represent a small group (usually newborns), and indications include severely low cardiac output states (e.g., critical aortic stenosis), pulmonary hypertension (e.g., obstructed total anomalous pulmonary venous drainage), and severe hypoxemia (e.g., transposition of the great arteries and pulmonary hypertension).²³⁻²⁵

Inability to Wean from Cardiopulmonary Bypass

The reported survival is poor for patients who are given ECMO because they were unable to wean directly from CPB in the operating room (i.e., without any period of stability off CPB).^{8,9,16,23} Issues such as primary myocardial dysfunction, pulmonary hypertension, severe hypoxemia, and refractory dysrhythmias are recognized as major factors in determining successful outcome, but unrecognized residual or irreparable defects are also important.⁹ Residual cardiac defects must be investigated in the operating room, using a combination of echocardiography and the careful measurement of oxygen saturations and intracardiac pressures. Ideally, only children with potentially reversible myocardial injury who cannot be weaned from CPB should be considered candidates for ECMO; however, this can be extremely difficult to determine in the operating room immediately after cardiac surgery. Additional considerations for use of ECMO in patients failing to wean from cardiopulmonary bypass after cardiac surgery include preoperative condition, intraoperative course, and the likelihood of being a transplant candidate. Severe hemorrhage is a major problem in the transition from the CPB circuit to the ECMO circuit. Although a lower activated clotting time (ACT; 160 to 180 seconds) can be used, small doses of protamine are often necessary to assist with the initial control of bleeding. We usually administer protamine in 1-mg/kg increments until a target ACT of 180 seconds is achieved. Infusions of antifibrinolytic drugs such as tranexamic acid (bolus of 100 mg/kg, followed by infusion at 10 mg/kg/hr), or ε-aminocaproic acid (bolus of 100 mg/kg, followed by infusion at 30 mg/kg/hr) should be considered. Exploration of the chest may be necessary, particularly if the bleeding persists at a rate greater than 10 mL/kg/hr and if problems with ECMO flow are encountered because of decreased venous cannula drainage from a tamponade-like effect. The large transfusion requirement can place a considerable burden on the supply of donor blood products. As an alternative, it is possible to connect a chest tube to cell-saver tubing to enable blood to be collected in the cell-saver reservoir and subsequently spun for retransfusion.

When a patient requires ECMO in the operating room, discussions with the patient's family must be clear and direct. Recovery of myocardial function should be expected within 2 to 3 days,²⁶ and if this is not evident, either listing for cardiac transplantation, if appropriate, or withdrawal from support must be considered.

After Cardiotomy

ECMO is an effective therapeutic option for infants and children who have had a period of relative stability after successful termination of CPB and exclusion of significant residual cardiac defects. Myocardial or respiratory failure causing a low cardiac output state, hypoxemia, or pulmonary hypertension and cardiac arrest are the major indications in this group. This group of patients is large, with reported good survival rates (60% to 70%), provided ECMO is instituted rapidly and effectively.^{8-10,16,23,27}

Cardiomyopathy, Myocarditis, and Bridge to Transplantation

Patients with acute fulminant myocarditis can be managed successfully with ECMO.^{5,28} Patients with fulminant myocarditis may arrive at the hospital undergoing full cardiac arrest, but more commonly they are in cardiogenic shock from an extremely low cardiac output state or they have hemodynamically significant dysrhythmias, including ventricular tachycardia or heart block. The heart is usually distended and is contracting poorly. Prompt institution of ECMO may allow sufficient resuscitation and stabilization to prevent end-organ injury and to enable the myocardium to rest while awaiting potential recovery. After ECMO is instituted, the heart must be fully decompressed, and urgent atrial septostomy or left atrial vent placement may be necessary.^{4,29} The heart might not begin to eject for the first 24 to 36 hours after ECMO is started, although recovery of electrical activity within the first few hours should be expected. If recovery of ventricular ejection is not evident within 2 to 3 days, ECMO can be continued either as a bridge to heart transplantation or as a bridge to alternative longer-term support with a VAD, if feasible.^{14,26,30-37} ECMO should be viewed as a short-term bridge to transplantation because of the limited donor availability and the time-related risks for complications, such as infection, bleeding, end-organ impairment, problems resulting from immobilization, and difficulties in maintaining adequate nutrition.^{32,38} In our experience at Boston Children's Hospital, the median time spent on ECMO awaiting heart transplantation is currently 140 hours (range, 26 to 556 hours), and only 50% of our listed patients have been effectively bridged. In a small number of older and larger children, ECMO has been used to initially resuscitate the circulation and end-organs, and if a donor heart has not become available by day 6 or 7 of ECMO, we have successfully transitioned from ECMO to longer-term VAD. Survival for patients with acute myocarditis supported with ECMO was recently reported to be 61% using data reported to the ECMO registry of ELSO. Because ECMO can provide good survival in any patients with acute fulminant myocarditis these patients should be cared for in facilities that have an ECMO or other MCS options.

ECMO also has been used to support the failing heart after transplantation. This may be necessary immediately after transplantation because of graft failure, usually in the setting of pulmonary hypertension and acute right ventricle failure of the donor heart. ECMO also is

effective in supporting the heart during periods of acute rejection.³⁴ The inflammation and myocardial edema are similar to that seen with fulminant myocarditis, and they lead to a similar spectrum of clinical features. ECMO allows the transplanted heart to decompress with decreased wall tension while antirejection therapy is increased. In our experience, survival to discharge for this indication is currently 64%, and the median duration of ECMO support is 4 days.

After In-Hospital Cardiac Arrest and CPR

Survival and outcome after in-hospital resuscitation of pediatric patients after a cardiac arrest continues to be extremely poor.³⁹⁻⁴⁴ Even in a highly monitored and resource-intensive area such as a pediatric intensive care unit (ICU), the survival rate after cardiac arrest has been reported to be only 9% to 31%. The duration of cardiac arrest and resuscitation is also an important determinant of subsequent outcome, and a number of reports have noted a critical threshold of approximately 15 minutes.^{39,40} ECMO has been successfully used to support children after prolonged periods of cardiac arrest that have been unresponsive to closed or open cardiac massage and all other usual interventions.^{4,8,20,21} Again, it is important to emphasize that the underlying lesion, in conjunction with the effectiveness of CPR while instituting ECMO, is a major determinant of outcome when mechanical support is used in this setting. Although the exact place of ECMO in the CPR algorithm remains ill defined, patients with a witnessed arrest and rapid institution of effective CPR, and who have no apparent recovery of cardiac function within 5 to 10 minutes of initiating resuscitation and no contraindications, may be suitable candidates for ECMO.

Determining the relative contraindications to ECMO support during active resuscitation attempts can be difficult (Table 109-5). Although not always possible, discussions regarding the use of ECMO in certain patients should be undertaken before an event occurs. We have been able to successfully use our rapid-response ECMO system during CPR in patients with acquired and structural heart disease, and in patients with double- or single-ventricle defects. In the latter group are neonates who have had a sudden, reversible event, such as acute thrombosis and obstruction to a systemic-to-pulmonary artery shunt after a Norwood procedure, and they have been readily resuscitated with ECMO. On the other hand, patients with cavopulmonary corrections (i.e., Fontan or bidirectional Glenn anastomosis) have been difficult to resuscitate using ECMO, in part because of limitations with cannulation, and an inability to maintain adequate systemic oxygen delivery and avoid cerebral venous hypertension during CPR with chest compressions. Although we have used ECMO in the resuscitation of patients with pulmonary hypertension and patients with systemic outflow obstruction, the severe limitation to cardiac output and oxygenations during CPR in these patients has meant that their overall outcomes on ECMO have been poor because of the development of severe end-organ injury.

Historically, successes using ECMO during active resuscitation and chest compressions (E-CPR) have been

TABLE 109-5 ECMO Support during Active Cardiopulmonary Resuscitation

Resuscitation Event	Considerations
Indications	
Event witnessed and monitored (e.g., tamponade, arrhythmia, systemic to pulmonary artery shunt, obstruction)	In-hospital event: ICU, OR, catheterization laboratory
Immediate and effective basic life support and CPR	Effective ECMO system and resources
No response to advanced life support in 10 min	Primed circuit (vacuumed or crystalloid)
Acceptable cardiac transplant candidate (e.g., fulminant myocarditis)	Equipment and personnel immediately available
Absolute Contraindications	
Event not witnessed or monitored	Out-of-hospital arrest
Known comorbidities that preclude listing for transplantation	Other congenital or chromosomal abnormalities
	Sepsis
	Central nervous system injury
	Renal failure
Relative Contraindications	
Effective ECMO support system not established	Circuit not immediately available
Known comorbidities that preclude effective resuscitation (e.g., pulmonary hypertension, systemic in-house outflow tract obstruction, semilunar or AV valve insufficiency, hypertrophic cardiomyopathy, cavopulmonary connection)	Equipment and personnel not trained for CPR

AV, Atrioventricular; CPR, cardiopulmonary resuscitation; ECMO, extracorporeal membrane oxygenation; ICU, intensive care unit; OR, operating room.

reported for a small number of series.^{8,20-22,45} A recent subanalysis of the ELSO Registry E-CPR data reports a 37% overall survival to discharge for patients placed on ECMO in this circumstance.^{4,5} To avoid significant delays, a rapid response ECMO system has been established at some institutions.^{4,21,22} The success of a rapid response system depends on a multidisciplinary approach, with equipment being immediately available, and the personnel with assigned roles being in-house, including cardiac surgery and intensive care fellows, respiratory and ECMO specialists, and trained nursing staff. At Boston Children's Hospital, a vacuum and CO₂-primed circuit using a roller pump and a 0.8- to 1.5-m² membrane oxygenator is available at all times and is suitable for children weighing up to approximately 15 kg. Even in older children, this circuit initially provides sufficient flow for resuscitation, stabilization, and hopefully prevention of end-organ damage, until a larger oxygenator can be spliced into the circuit. Generally, however, for older children and adults, a new circuit with a hollow-fiber membrane is used, which takes little time to de-air and

can be established within 15 minutes. Once the patient is in stable condition with ECMO, the hollow-fiber membrane can be exchanged for a conventional membrane for longer-term support as necessary. An alternative rapid response system has been described, which uses a heparin-coated circuit, centrifugal pump, and a hollow-fiber membrane with a priming volume of only 250 mL and a priming time of only 5 minutes.

In postoperative cardiac patients, atrial and aortic cannulation via a reopened sternotomy is usually the access mode of choice. In other patients, experienced practitioners can rapidly gain access via the neck vessels. During resuscitation, the circuit is primed with crystalloid supplemented with 5% albumin. We do not wait for donor blood to be crossmatched to complete a blood prime of the circuit because of the inevitable delay. We prefer to reestablish organ perfusion as soon as possible, and once ECMO is satisfactorily established, blood products can be added or the priming crystalloid can be removed via hemofiltration. To assist with neurologic protection, where possible we maintain mild hypothermia (34° to 35° C) for the first 12 hours after administering ECMO during active resuscitation. Using the rapid response system, we can be ready to place a patient on ECMO within 15 minutes, and the main limitation is then the problems associated with cannulation. We have deployed the rapid response system during active resuscitation in more than 170 children since 1996, and we have been able to achieve a survival-to-discharge rate of 51% in this group of patients.⁴

TECHNICAL ASPECTS OF ECMO CANNULATION

Cannulation for ECMO begins with preemptive maneuvers that will ensure expedient delivery of this lifesaving measure. Prior planning is key and can ensure smooth cannulation in a situation that may be chaotic. The first step is identifying patients in unstable condition and who may require institution of ECMO. If during the evaluation of the patient by the treating team in the ICU, a patient is believed to be at risk of hemodynamic or respiratory deterioration enough to require AV or VV ECMO, then it is important to communicate with the ECMO team. This communication includes the surgeon who will be performing the procedure and the ECMO specialists who will be priming and running the circuit. This will give them time to know patient details that will help to develop a cannulation and support strategy. Heparin can be drawn up and prepared. A range of cannulas can be preselected. An appropriately sized circuit can be prepared. The blood bank can be alerted. Identifying potential ECMO patients early can also allow for calm and sober discussion about the appropriateness of the intervention.

For the cannulating surgeon, intimate knowledge of the systemic venous and arterial anatomy, especially the patency of the peripheral vessels that may be considered for access, is vital. If peripheral cannulation is to be performed, it is appropriate to have confirmatory imaging obtained beforehand. In our cardiac ICU, we maintain a

sheet of paper by the bedside detailing which peripheral arterial and venous access points are patent. This sheet can prevent unnecessary delays from cutting down on a vessel that is stenosed, scarred, or not patent. For patients with congenital cardiac anomalies, it is important to know in detail the topography of the heart, the intracardiac anatomy, and systemic venous arrangement. These details can have bearing on the cannulation strategy. For example, if a patient has a single left superior vena cava (SVC), venous access should be ideally obtained in the left neck. A patient with unoperated hypoplastic left heart syndrome may occasionally need to be cannulated centrally in the duct or main pulmonary artery for arterial inflow.

Access

Cannulation access can be central or peripheral. By central cannulation, we mean access to the intrathoracic structure to cannulate. This access can be gained through a sternotomy or, less commonly, a thoracotomy. The indications for central cannulation include postcardiotomy, open chest, small neonate or infant, need for supraphysiologic flows, when peripheral access cannot sustain adequate ECMO flow, and when no other access is available. Venous drainage can be obtained via the right atrium, superior vena cava, inferior vena cava (IVC), or even the pulmonary artery. Rarely, the only access for return to the pump is from the pulmonary venous atrium. Arterial perfusion is most commonly performed into the aorta, although arch vessels can be accessed. Direct cannulation of the artery is usually performed, although if time allows, placing a graft on an arch vessel is feasible and has the advantage of minimizing the risk of occluding that vessel.

The advantages of central cannulation are that it is the easiest access after sternotomy, it provides the most reliable cannula position, it gives the best venous drainage and therefore most optimal flows, it is easy to vent the left side, and it can be easily converted to cardiopulmonary bypass. The disadvantages of central cannulation are that it is labor intensive, it is better done in the operating room, it is not ideal if the chest is closed in an emergency, there may be more bleeding, and there is the risk of mediastinal infection. Central cannulation can be very difficult if a previous sternotomy was performed greater than 2 weeks prior. In this circumstance we may elect to cannulate peripherally, even in the context of recent cardiac surgery.

Peripheral cannulation is cannulation of the extra thoracic vessels. This can be performed in the neck for neonates, infants, children (including teenagers), and young adults. The subclavian and axillary vessels can be used occasionally in older patients. The other common point of access is the femoral artery and vein. Rarely, the iliac vessels, abdominal aorta, or abdominal cava may be used. The indications for peripheral cannulation include an arrest situation, a contraindication to central cannulation, and in some circumstances after cardiotomy. Contraindications to peripheral cannulation include a known small vessel and vessel stenosis or occlusion. Previous cannulation of a peripheral vessel is not an absolute

contraindication to repeat access, as long as the vessels are known to be adequate in size and patent.

Access to the peripheral vasculature can be open or closed. Open technique involves a surgical cutdown to visualize the vessel directly. Indications for vessel cutdown include surgeon preference, an arrest situation, uncertainty about vessel patency, or failure of percutaneous access. The advantages of open technique include certain identification of vessels, the ability to assess the vessels, less risk of injury to the vessels and adjacent structures, and the ability to insert larger cannulas. We believe that in the context of cardiopulmonary resuscitation with ongoing cardiac massage, cutdown is the most reliable way to differentiate an artery from a vein. Both vessels may have pulsatile deoxygenated blood during cardiac massage, making needle identification unreliable. Disadvantages of the cutdown technique include the time to perform the procedure, the need for available equipment and expertise, bleeding, infection, and the potential need for secondary intervention to decannulate. Once the vessels are identified by cutdown, the cannulas can be introduced using arteriotomy and venotomy or direct Seldinger technique.

Closed access to the peripheral vessels is also referred to as *percutaneous access*. This is commonly done with the Seldinger technique. It is best performed in a patient in stable condition or during an arrest situation when the vessels have already been identified by previous vascular access. Contraindications to percutaneous access are known obstruction of the vessel, percutaneous cannulas not being available, and a small patient (neonate, infant, small child weighing < 15 kg). The advantages of closed access is that it is less technically demanding, less personnel and equipment are required, it can be faster, it is more hemostatic, and it is usually a single procedure. Disadvantages are that it is a blind technique (unless ultrasound is available); it is unreliable for distinguishing an artery from a vein with cardiac massage; it is associated with the use of smaller cannulas, which can compromise flow; it is difficult to perform in a small patient; and it makes the open technique more difficult if there is a technical failure.

Special Circumstances

Single Ventricle

Patients with single-ventricle physiology can be cannulated centrally or peripherally, depending on the circumstances. When performing the first stage of palliation, we use antegrade cerebral perfusion through a graft anastomosed end-to-side onto the innominate artery. At the end of the procedure, the graft is clipped at the base and left long. If ECMO support is needed, the graft can be cannulated for arterial inflow. It is extremely important to flush the graft to remove any debris or thrombus before placing a cannula.

Patients with a modified BT shunt may require the shunt to be clipped partially to maintain adequate perfusion pressure, while receiving ECMO. Clipping the shunt completely risks thrombosis of pulmonary arteries and lung ischemia because of unreliable bronchial

circulation. Despite narrowing of the BT shunt, ECMO flows may need to be supraphysiologic to maintain adequate perfusion.

Patients with a superior cavopulmonary connection present a challenge when cannulated through the neck. Care must be taken to avoid perforating the pulmonary arteries by advancing the venous cannula too far. Obtaining sufficient venous drainage for adequate support is difficult and, therefore, additional sites for drainage may be necessary. Femoral cannulation is usually not an option when the child is small. Central cannulation may be necessary to get adequate flows.

Patients with a Fontan circulation needing ECMO may present at a wide range of ages. It is ideal to place the venous drainage cannula in the Fontan pathway. However, whether doing cervical or femoral cannulation, it may be difficult to negotiate the cannula into the pathway. Occasionally, image guidance may be necessary. The presence of aortopulmonary collaterals may require supraphysiologic flows to maintain adequate perfusion.

Femoral Cannulation

Cannulation of the femoral artery and ipsilateral vein risks ischemia of the lower extremity. One option is to cannulate the contralateral vein. If the artery and vein are cannulated on the same side, we routinely place a small distal perfusion catheter on the distal femoral artery. It may be advanced into the superficial femoral vein or the profunda femoris. An additional maneuver is to place a distal drainage cannula in the femoral vein, to avoid suffusion of the leg.

Neck Cannulation

Internal jugular venous drainage can be optimized by placement of a small catheter up toward the head for cephalic drainage. It can contribute a significant amount of venous return obviating the need for an additional cannula elsewhere. Cephalic drainage is especially important to avoid cerebral edema, if the contralateral internal jugular vein is obstructed.

Venting

It is paramount to have an adequately decompressed ventricle while receiving ECMO to maximize the chances of ventricular recovery and to avoid lung injury from left atrial hypertension. The ventricle must be able to handle the pulmonary venous return. One must always be aware that significant left atrial hypertension can occur, even in the presence of apparent ventricular contractility. However, if there is any ventricular distention by echocardiography, this should be dealt with urgently. In a child, often all that is necessary is to create or enlarge an interatrial communication, to allow left to right shunting. This can be done in the catheterization laboratory. Alternatively, a vent can be placed into the left atrium; into the ventricle across the mitral valve, or into the ventricle itself. Any of these can be done surgically during central cannulation. A vent can also be placed across an interatrial communication in the catheterization laboratory. In

ECMO, Extracorporeal membrane oxygenation.

children, vents are prone to thrombosis because of their small size, long length, and limited flows.

Conduct of Cannulation

ECMO cannulation is often done under emergent circumstances during a resuscitation in an ICU. It is important for the cannulating surgeon to remain calm in the face of chaos. Communication with the entire team during the procedure is key. If CPR is ongoing, it must be stopped at the request of the surgeon. Timing of heparin delivery must be communicated clearly to the ICU team by the surgeon. The surgeon communicates with the ECMO specialists regarding cannula choice and required pump flows.

The importance of adequately positioning the patient for access to the neck, chest, or groin, as necessary, cannot be overstated. Necessary equipment for the procedure must be immediately available, ideally in the ICU. A head light is invaluable, as well as operating loupes for small children. Sometimes, the surgeon will have to begin the procedure with an inexperienced assistant and without an operating room team. The surgeon must be able to direct their assistant precisely, and be very familiar with the organization of the available surgical instruments. To mitigate the stress of cannulation, simulation team training with "cannulatable" models may be helpful.

Circuit and Cannula Management

The ECMO system circuit includes a reservoir, membrane oxygenator, and heat exchanger. The ECMO and cannula guidelines used at Boston Children's Hospital are shown in Tables 109-6 and 109-7. The circuit volume can range from approximately 350 mL (in neonates) to 2 to 3 L (in adults). Before cannulation, heparin is administered and the ACT is usually maintained between 180 and 200 by continuous heparin infusion. Occasionally,

TABLE 109-7 ECMO Cannula Size According to Patient Weight

ECMO, Extracorporeal membrane oxygenation.

the ACT is maintained at a somewhat lower level in the presence of significant bleeding. At times, large doses of drugs such as heparin, fentanyl, or midazolam may be necessary because of binding to the circuit and oxygenator, or because of dilution by bleeding. Perfusion flow rates in infants and small children typically range from 100 to 150 mL/kg/min during full circulatory support. Blood products are administered to keep the hematocrit level between 35% and 45%, typically, and the platelet count greater than 100,000/mm³.

Arteriovenous cannulation is usually used for cardiac ECMO, although venovenous bypass can be used in patients who require ventilatory support only. In the immediate postoperative period, mediastinal cannulation, using single right atrial and ascending aortic cannulas, is often preferable because cannulation can be rapidly achieved, along with left atrial decompression if necessary. For the risk of infection to be reduced further, if possible, the skin is closed over the cannulas and the chest, or a surgical Silastic membrane is used instead. Alternatively, the internal jugular vein and carotid artery can be used, with the potential advantage of less bleeding, a more stable cannula position, and, by avoiding an open sternum, a possible reduction in the risk for infection. If neck cannulation is used, the carotid artery can be either

ligated or repaired. Despite concerns about uneven cerebral blood flow, ligation seems to be surprisingly well tolerated clinically, but reconstruction requires long-term follow-up because of the increased risk of stenosis at the anastomotic site.^{46,47} The femoral vessels in infants and young children might not accommodate cannulas of sufficient size to permit complete circulatory support. However, these sites have been used occasionally to provide resuscitation and stabilization in acute emergency situations (e.g., in the cardiac catheterization laboratory) or when femoral access has already been established.

Children with complex structural cardiac defects may have associated abnormalities with systemic venous damage (e.g., heterotaxy syndromes), or they may have undergone previous cardiac catheterization or interventions that have caused occlusion of femoral vessels. Therefore, their venous and arterial anatomy must be well known and well documented to prevent inappropriate cannulation attempts.

The daily management of a patient on ECMO or other forms of extracorporeal life support requires a meticulous assessment of cardiorespiratory function, end-organ perfusion and injury, evolving complications such as bleeding or sepsis, and the mechanics of the ECMO circuit.⁴⁸ If a patient fails to wean from ECMO or there is a delay in anticipated recovery of myocardial function, the possibility of a residual surgical problem must always be considered. This is usually difficult to diagnose by echocardiography alone, and cardiac catheterization (diagnostic or interventional) should be considered.

Assessing the adequacy of flow and systemic perfusion soon after initiation of ECMO is of paramount importance. Inadequate flow states or persistent hypotension despite perceived adequate flow requires immediate analysis and intervention (Table 109-8). Venous cannula malposition or inadequate size limits venous drainage if a roller pump is used, thereby contributing to circuit chatter and bladder collapse. This should be addressed immediately, and the venous cannula should be repositioned, an additional venous cannula placed, or the existing cannula upsized. When ECMO flow appears inadequate to meet the needs of the patient and limited venous drainage restricts additional flow, interpretation of arterial and atrial pressures may aid the formulation of a differential diagnosis. For example, a low atrial pressure and inadequate venous drainage may represent hypovolemia from ongoing or unrecognized bleeding. On the

other hand, high atrial pressures with inadequate venous drainage may represent tamponade physiology that requires surgical exploration in a postoperative patient, or it may reflect left ventricle overdistention from inadequate decompression or aortic valve regurgitation. Elevated postmembrane pressures may reflect malposition of the arterial cannula or a cannula that is too small and needs to be revised. Elevated premembrane pressure (e.g., >350 mm Hg) at normal flows without change in postmembrane pressure, or evidence of a blood-gas leak, constitutes membrane oxygenator dysfunction and may dictate oxygenator replacement. Extensive thrombus and consumptive coagulopathy with hypofibrinogenemia and thrombocytopenia are other indications for circuit replacement.

Echocardiography, especially transesophageal (and occasionally cardiac catheterization), is used to assess cardiac structure and contractile function and to detect residual lesions and the need for left atrial decompression.^{29,49} Venting the left atrium may be necessary to lower the left atrial pressure and decrease left ventricular wall stress, thereby minimizing ongoing myocardial injury. Adequate decompression can be assessed early by echocardiography and signs of pulmonary edema. Strategies to assist with decompressing the ventricle include placing a vent in the left atrium by direct placement through an open chest, a transcatheter approach in the catheterization laboratory,²⁹ or by creating an unrestricted atrial septal defect via septostomy and then augmenting ventricular ejection with inotropic agents.

Once ECMO is successfully established, inotropic support is usually reduced, and vasodilators may be required to improve systemic perfusion and enable appropriate flow rates. The fraction of inspired oxygen (FiO₂) and ventilatory support also are decreased to a low respiratory rate (5 to 10 breaths/min), low peak inspiratory pressures (20 to 25 cm H₂O), and low levels of positive end-expiratory pressure to preserve lung volume and to limit inactivation of alveolar surfactant.

Considerations regarding cannulation and flow rates once the patient is receiving ECMO may be specific to the underlying cardiac defect or surgical repair. For example, the management of an aortopulmonary shunt is critical in patients with single-ventricle physiology. Systemic and pulmonary flow should be balanced by either partially clipping the shunt or using high ECMO flows. With ECMO, circuit flows up to 200 mL/kg/min (or even greater) are usually necessary to maintain adequate systemic perfusion while accounting for runoff into the

TABLE 109-8 Causes of Inadequate ECMO Flow and Perfusion

	Cannula	Anatomic	Physiologic
Inadequate venous drainage	Too small Malpositioned Air occlusion	Heterotaxy syndromes Vessel occlusion or stenosis	Hypovolemia Tamponade
Inadequate systemic perfusion	Too small (high postmembrane pressure) Malpositioned Occlusion	Aortic valve regurgitation Vessel stenosis	Nonvented, distended ventricle Systemic vasoconstriction or vasodilation

ECMO, Extracorporeal membrane oxygenation.

pulmonary circulation through the shunt. Although partial temporary narrowing of the shunt may be advisable in some circumstances, it is unwise to completely occlude the only source of pulmonary blood flow to the pulmonary endothelium. It is possible to bypass the membrane oxygenator in patients after the Norwood procedure with a modified Blalock-Taussig shunt in patients without lung disease if higher flows are maintained and the shunt is patent.⁵⁰ This maneuver simplifies the circuit and can permit the use of less of heparin. ECMO thus effectively becomes a VAD.

Problems related to cannula placement and adequacy of venous drainage may be particularly evident in patients with complex venous anatomy, such as heterotaxy syndrome, and in patients with a cavopulmonary connection. The site of cannulation is affected by vessel patency, and the underlying physiology might influence the number of venous cannulas used. For example, patients with a superior cavopulmonary anastomosis (bidirectional Glenn shunt) as the primary source of pulmonary blood flow frequently require separate venous drainage of the SVC and IVC, unless there is congenital interruption of the infrahepatic IVC with drainage of lower body blood to the azygos vein. In the latter case, a single venous cannula in the SVC might be sufficient. On the other hand, placement of a cannula in the SVC may be detrimental in patients with bidirectional Glenn shunt physiology because of the potential for reduced cerebral venous drainage and therefore decreased cerebral perfusion. This is also a concern for patients with Fontan physiology; although it may be possible to achieve adequate drainage with a venous cannula placed in the Fontan baffle, an additional SVC catheter is often necessary to achieve the desired or necessary flow rates on ECMO.⁵¹

Weaning from Extracorporeal Membrane Oxygenation

The strategies for weaning from cardiac ECMO are often quite different from those used to wean patients who are receiving ECMO for respiratory support. For patients with structurally normal hearts who require ECMO support for respiratory illness, the ability to wean depends on resolution of the primary pulmonary process, often with little need for support of the myocardium beyond moderate inotropic support, fluid and electrolyte management, and nutritional support. Once lung compliance and gas exchange are normalized, improvement of the lungs on the chest radiograph is apparent, and a stable circulation with sufficient negative fluid balance has been achieved, the patient is sedated, paralyzed, and fully ventilated, and the ECMO circuit is clamped.

Before weaning a patient from ECMO used for circulatory support, an understanding of the underlying cardiac physiology and cardiorespiratory interactions and an appreciation for the expected range of oxygen saturation levels are important. Because of the increased risk of complications and mortality in patients with cardiac disease when the duration of MCS extends beyond 7 days, consideration as to when and how to wean cardiac patients from ECMO should begin once circulatory

stability has been established. The disease process and circumstances resulting in hemodynamic failure or cardiac arrest can influence the expected duration of mechanical support. For example, patients who fail to separate from CPB after cardiac surgery as a result of severe pulmonary hypertension usually respond to a period of 24 to 48 hours on ECMO with inhaled nitric oxide (NO) therapy and inotropic support of the right side of the heart. Similarly, patients who have a low cardiac output state or suffer cardiac arrest after cardiac surgery may have residual defects that allow rapid weaning and decannulation soon after reoperation. The likelihood of recovery of ventricular function should be decided within the first 48 to 72 hours so that cardiac transplantation status can be ascertained. ECMO instituted for catheter intervention or arrhythmia ablation procedures may be discontinued within hours of patient cannulation.⁵² In contrast, patients with severe cardiomyopathies or those awaiting heart transplantation may require mechanical assistance for a much longer period. Patients with severe bronchiolitis because of respiratory syncytial virus complicating repair of congenital heart disease on CPB typically require 2 to 3 weeks of ECMO support for respiratory failure.

Patients requiring cardiovascular support with ECMO are partially weaned within the first 48 hours for assessment of myocardial function by echocardiography and hemodynamic evaluation. An acceptable PaO₂ obtained while the ECMO circuit is clamped varies substantially according to the underlying anatomy and pathophysiology. If transthoracic cannulation was used and problems with bleeding were encountered during the ECMO run, the mediastinum may require exploration before or during the weaning process. If only a short period of reconditioning of the myocardium is anticipated, the patient is frequently sedated and paralyzed, dopamine infusion is increased to 5 to 10 mg/kg/min, intravascular volume status is optimized, and ventilator settings are adjusted according to lung compliance and expected arterial O₂ saturation. ECMO flow is decreased by 25% to 50% over a period of time until the circuit is clamped. Volume is infused to achieve appropriate preload. Echocardiographic assessment of ventricular systolic function, valvular function, systemic and pulmonary outflow obstruction, and location and direction of intracardiac shunts is useful before weaning, as well as if there is a change in hemodynamics after the circuit has been clamped. Arterial blood gases, serum lactate levels, and systemic and mixed venous oxygen saturation levels are important guides to the stability of the circulation, ventilation, and adequacy of perfusion after the circuit has been clamped. Decannulation from ECMO is undertaken once the patient has maintained a stable circulation and acceptable gas exchange for a period of up to 4 hours.

INTRA-AORTIC BALLOON COUNTERPULSATION

Intra-aortic balloon pump (IABP) counterpulsation is commonly used for the treatment of myocardial failure in adults, especially in the postoperative period. When

used in infants and children, however, results have been disappointing, with survival rates of less than 50%.⁵³⁻⁵⁵ Many factors contribute to the reduced efficacy in children. Heart failure in pediatric patients is often caused by either right ventricular or biventricular dysfunction, conditions in which the IABP is not effective. Placement of an IABP in the pulmonary artery has been reported but is usually challenging, in part because of the small balloon size required and the increased compliance of the pulmonary artery.^{56,57} The relatively rapid heart rate of infants and small children and the variable delay between aortic valve closure and the appearance of the arterial tracing on the oscilloscope make effective timing of inflation and deflation more difficult. At heart rates greater than 160 beats/min, the IABP is often reduced to a 1:2 or even 1:4 pumping frequency to facilitate cycle timing, at the same time decreasing the effectiveness to 50% to 80%.^{58,59} The aorta is typically more distensible in both infants and children; therefore, both coronary flow augmentation during diastole (balloon inflation) and afterload reduction during systole (balloon deflation) are likely to be less. In addition, the effect of diastolic augmentation on normal coronaries, prevailing in the pediatric population, has been questioned.^{60,61} Severe cyanotic heart disease in children can be accompanied by extensive aortopulmonary collateral vessels, which permit shunting of blood into the pulmonary circulation during balloon inflation, thus reducing augmentation of coronary blood flow.

The smallest balloon system available for children is 2.5 mL, which can be used for neonates as small as 2 kg. In general, for children weighing less than 30 kg, a balloon volume of 0.5 mL/kg is recommended. For balloon inflation, helium is preferred over CO₂, as it allows a faster pneumatic response because of its low density. Interestingly, the incidence of vascular complications, such as bleeding, emboli, or limb ischemia, correlates well with the adult population, where it is reported in 10% to 20% of cases. Other potential complications are infection, renal dysfunction, mesenteric occlusion or embolism, and cerebrovascular accidents.^{62,63}

Numerous technical improvements have been made to enhance efficacy in the pediatric population. These improvements include modified pumping consoles and small-sized catheters, improved tracking at higher heart rates, more rapid inflation and deflation, and the use of M-mode echocardiography for cycle timing.⁶⁴ Further study is necessary to evaluate the importance and continued role of IABP support for pediatric patients, particularly in the face of growing availability of other modes of circulatory support.

VENTRICULAR ASSIST DEVICES

The experience with VADs in infants and children remains relatively small when compared with that in adults, but it has been growing steadily over the last 5 years. As with adult patients, VAD support is useful as a bridge to transplantation, and it allows recovery of end-organ function, elimination of edema, and improvement in nutrition, and it provides rehabilitation of critically ill

patients. An important component of these benefits is the ability of the device to allow extubation and ambulation, which cannot be accomplished currently with ECMO and centrifugal VADs.

The main problem in adapting the VADs used for adult patients had been size limitations and flow requirements; the risk for thromboembolic complications increases with lower flow. In pediatric patients, the selection of pump sizes carries particular importance. A pump that is too small can result in less than adequate cardiac output, and when run at higher rates, it risks inducing significant hemolysis. However, if the pump is too large and is then run at rates too slow, it can result in increased risk of thrombus formation and can be associated with persistent systemic hypertension.

In addition to the obvious variability in size, there are other factors that provide distinct differences between adult and pediatric recipients. These factors include the anatomic variations that are encountered in complex congenital heart disease, the potential of growth, and the unique susceptibility to anticoagulation that children can exhibit. Because of these differences, VAD therapy in children imposes unique challenges that must be anticipated with its application.⁶⁵

As with ECMO, the selection of appropriate candidates for VAD therapy is crucial, and surgical problems or residual defects should be excluded where possible. Whereas ECMO can be instituted by peripheral cannulation of neck or femoral vessels, the currently available VADs require direct cannulation of the heart through a sternotomy. The reported survival rates with VADs are similar to those achieved with cardiac ECMO,^{12,26,66,67} and left VADs (LVADs), right VADs (RVADs), or dual-support VADs (biVADs) can successfully support the circulation, depending on the circumstances. The majority of reported pediatric patients have received LVADs, which have been particularly beneficial in patients with decompensated cardiomyopathy, an ischemic myocardium secondary to an anomalous origin of left coronary artery from the pulmonary artery, and for "retraining" of the poorly prepared left ventricle after an arterial switch procedure.⁶⁸⁻⁷⁰ There are also increasing numbers of case reports describing the use of VAD support in patients with complex congenital heart disease such as single ventricles, including the Fontan circulation (Fig. 109-2).^{71,72}

The advantages of the VAD circuit over ECMO are that the former is relatively simple in design, takes less time to prime, and requires little technical assistance once established. Bleeding complications and requirements for blood products and platelet transfusions are generally less in patients on VADs compared with those on ECMO.^{12,47} Requirement for heparinization and maintaining a prolonged ACT is proportionately less. Because of the lower complication rate, a VAD is more suitable for long-term support as a bridge to transplantation.^{11,12,73}

Another possible advantage of VADs is superior left ventricular drainage and unloading, a prerequisite for myocardial rest and potential recovery.^{11,47,74} While adequate ventilation of the left atrium on ECMO is possible, it does not provide equivalent ventricular decompression when compared with a VAD. Whenever a patient is connected to a VAD, the response of the

FIGURE 109-2 ■ Use of a ventricular assist device after a Fontan operation.

unsupported ventricle must be closely monitored. Ideally, the reduction in left atrial pressure during LVAD support, associated with adequate decompression of the left ventricle, reduces pulmonary venous and arterial pressures and improves right ventricular function. Unfortunately, based on adult data, right ventricular failure can still develop in up to 25% of patients, especially in LVAD-supported patients with ischemic myocardium, with pre-existing anatomic defects, or after prolonged bypass procedures.⁷⁵⁻⁷⁷

Nonpulsatile Devices

Early in the pediatric VAD experience, most VADs for small children were nonpulsatile systems, either roller pumps or a centrifugal pump such as the Bio-Medicus circuit (Medtronic; Bio-Medicus, Minneapolis, MN). Although these pumps are now mostly of historical value, excellent results were reported using them to support infants and children (<6 kg).⁴² The centrifugal pump, in which blood is entrained by creating a vortex using spinning cones, is highly sensitive to changes in preload and systemic resistance. This is useful when adapting inotropic support or afterload reduction in preparation for weaning. Furthermore, the pump is designed to create constant flow rather than pressure, so the risk of accidental line disruption is reduced. The Bio-Medicus centrifugal pump can be used in infants and older children, and because gravity is not needed to achieve venous drainage, the pump housing can be placed close to the patient and is readily portable.

In 2004, the DeBakey VAD Child (Micromed Technology, Houston, TX) became the first VAD to receive U.S. Food and Drug Administration (FDA) humanitarian device exemption approval for use in children (with a body surface area [BSA] of 0.7 to 1.5 m²). It is a fully implantable axial flow pump that is electromechanically coupled to its power source. The inlet flow is achieved by apical ventricular cannulation with outlet cannulation of the ascending or descending aorta. Early results for the device had been mixed and the experience is still limited. Hemolysis is a concern with axial flow and roller pumps, and this possible complication needs to be monitored closely.^{78,79} Other devices, such as the PediVas

(Levitronix Centrimag and Maquet Rotaflow), and more minimally invasive devices (e.g., the Tandem Heart) and impeller-type pumps (e.g., the Impella VAD) are currently under evaluation in pediatric patients, mostly as temporary devices as a bridge to decision or bridge to recovery.

Pulsatile Devices

Several pulsatile devices (both paracorporeal and implantable) used in adult patients have been adapted for use in older children (BSA > 1.2 m²) to achieve a flow rate of at least 2 L/min. Successful use of the HeartMate LVAD (Thermocardiosystems, Woburn, MA) has been reported in adolescents with a BSA ranging from 1.4 to 2.2 m².⁸⁰ The implantation of the paracorporeal Thoratec VAD (Thoratec Laboratories, Berkeley, CA) has been used extensively in teenagers and has been reported in children as young as 11 years.⁸¹ Other such paracorporeal devices include the Abiomed AB 5000. In our experience at Boston Children's Hospital, the smallest patient to undergo implantation of this device had a BSA of 1.3 m². The reported incidence of thromboembolic events with the adult devices is higher in the pediatric population than in the adult population.

The Berlin Heart VAD (Berlin Heart AG, Berlin, Germany) and the Medos HIA-VAD (Medos Medizintechnik AG, Stolberg, Germany) are paracorporeal pneumatic devices for longer-term support in infants and small children.^{73,82-85} Both are produced in various sizes. Both are pneumatically driven pumps that can deliver varying stroke volumes that can be matched to even the smallest pediatric patients. A measured amount of compressed air is delivered through a pneumatic line that then compresses the ventricular chamber or bladder, thereby enforcing ejection of blood. Diastolic pump filling is achieved with gravity or gentle suction. Because of the high resistance of the small-bore cannulas, positive systolic pressures of up to 350 mm Hg and negative suction of 100 mm Hg at pumping rates of up to 140 beats/min may be necessary, increasing the power requirements for the driving unit considerably, compared with adult devices. Polyurethane trileaflet valves with low transvalvular pressure gradients and rapid closure, as well

FIGURE 109-3 ■ The Berlin Heart Excor ventricular assist device.

as the use of heparin-coated (Carmeda) systems, reduce the thromboembolic risk, one of the major problems associated with VADs in children.⁸⁶

Berlin Heart

The Berlin Heart Excor VAD (Berlin Heart AG) was the first commercially available ventricular assist system designed specifically for pediatric patients. First developed in Germany, it has been the paracorporeal device most frequently implanted in children in the United States. The Excor pediatric VAD is an extracorporeal, pneumatically driven, pulsatile VAD designed to support the right or left ventricle (or both) synchronously or asynchronously. Cannulas connect the blood pumps to the atrium or ventricle and to the great arteries, and an electropneumatic driving unit provides alternating air pressure to the blood pumps through drive lines (Fig. 109-3). The blood pump is divided into an air chamber and a blood chamber by a polyurethane membrane, and pulses of air pressure move the membrane, allowing both filling and emptying of the blood chamber. Polyurethane valves are located at the inlet and outlet positions of the blood pump, thus ensuring unidirectional blood flow. The blood pumps are available in six different sizes, with stroke volumes of 10, 25, 30, 50, and 60 mL that can be matched for all patient ages and sizes (Fig. 109-4).

Being a pulsatile and mobile support system, the Berlin Heart enables patients to be extubated from mechanical ventilation, to discontinue sedative and paralytic drugs, and to transition to enteral nutrition. A major benefit is the improvement in end-organ function, particularly renal and gut function and, in many cases, patients can be ambulatory. This benefit is particularly important because patients are able to undergo cardiac transplantation in a much better overall condition, which hastens their subsequent recovery after heart transplantation.⁸⁷

The device was first approved in Europe in the 1990s, and experience suggests that the Berlin Heart can provide effective ventricular support for a number of months in children as small as 3 kg. The North American experience dates back to 2000, when the first implantation was performed at the University of Arizona. In early 2007, a multicenter North American trial evaluating the Berlin Heart Excor Pediatric VAD was initiated. The 12-center study, which included two Canadian centers, was designed to provide basic safety information needed to support FDA approval of the device under a formal

FIGURE 109-4 ■ Selection of pump size matched to patient weight for the Berlin Heart.

investigational device exemption status. This clinical trial was a prospective, multicenter, single-group cohort study comparing children who had implantation of the Excor Pediatric VAD (Berlin Heart) as a bridge to transplantation, with a historical control group of children who received circulatory support with ECMO. Forty-eight Berlin Heart patients were matched with 48 patients from the ELSO Registry. The Berlin Heart patients were divided equally into two cohorts: cohort 1 with BSA < 0.7 m² and cohort 2 with BSA of 0.7 to 1.5 m². For cohort 1, the median time to death or weaning from the device with unacceptable neurologic outcome had not been reached at 174 days. By contrast, the matched ECMO group median time to death was 13 days. For cohort 2, the median time was 144 days, and the matched ECMO group was 10 days. For cohort 1, at 174 days, 88% had undergone transplantation and 12% had died or had an unacceptable neurologic outcome after device wean. In the matched ECMO group for cohort 1, 35% had died at 21 days and none were alive receiving support. For cohort 2, at 192 days, 92% had undergone transplantation or weaning from device, while 8% had died. In the matched ECMO group for cohort 2, 33% had died at 30 days and none were alive on support. Serious adverse events included major bleeding (cohort 1, 42% and cohort 2, 50%); infection (63% and 50%, respectively); and stroke (29%, in each). Although not a randomized trial, this study demonstrated that survival to transplant

or recovery was better with a VAD compared with ECMO. Nevertheless, the rate of complications with the Berlin Heart was significant. Most concerning was the 29% stroke rate. The device received humanitarian device exemption approval in December 2011.

Although the Berlin Heart is currently the most widely used pediatric VAD available for longer-term support of the circulation in children, a number of alternative devices now under investigation will increase the treatment options and, it is hoped, improve outcomes for children with acute and chronic heart failure. There are also a multitude of other MCS devices that are being used in children with increasing frequency through other regulatory pathways. The FDA permits VAD implantation in children under the following pathways: (1) off-label use of an otherwise FDA-approved adult device, (2) compassionate use of investigational adult devices, (3) emergency use of investigational device on a case-by-case basis, and (4) use of a device fabricated from FDA-approved components (e.g., ECMO circuits). Once medical devices are approved for use in adults, they can then be used in children depending on how the device is labeled (i.e., whether there is a specific weight, size or age restriction listed for the device). Currently approved VADs in adults have no restriction specifically outlined for age or size; therefore, they can be used in children. Off-label use of medical devices is a common occurrence in the field of pediatric MCS. It entails the use of a device outside the population or purpose for which the device's safety and efficacy profile was originally evaluated. For short-term support (temporary MCS), the following devices have been used in children: the TandemHeart (Cardiac Assist, Inc., Pittsburgh, PA) percutaneous VAD, the Rotaflow (Maquet Medical Systems, Wayne, NJ), the Centrimag (Thoratec Corporation, Pleasanton, MA), and the Abiomed Impella 2.5/5.0 (Abiomed, Inc., Danvers, MA). For long-term support (durable MCS), the following devices have been used primarily in larger children and adolescents: the HeartMate II (Thoratec Corporation), the HeartWare HVAD (HeartWare, Inc., Framingham, MA), and the Syncardia Total Artificial Heart (TAH; Syncardia Systems, Inc., Tucson, AZ).

Recognizing that pediatric mechanical support represents an unmet need in the United States, the National Heart Lung and Blood Institute (NHLBI) under its Pediatric Circulatory Support initiative, awarded five contracts in 2004, exceeding \$20 million, to support the preclinical development of innovative circulatory support devices designed specifically for infants and smaller children.⁸⁸ As a follow-up to its Pediatric Circulatory Support Program initiative, the NHLBI awarded four contracts totaling \$23.6 million in January 2010 to begin preclinical testing of devices to help children with congenital heart defects or those who develop heart failure. The 4-year program is called *Pumps for Kids, Infants, and Neonates (PumpKIN)*. It includes three of the original five contractors from the previous 2004 NHLBI Pediatric Circulatory Support Program and another. As such, the PumpKIN program is the next phase of NHLBI support for the development and clinical realization of novel pediatric circulatory support devices. The program's goal is to complete the needed investigational device

exemption clinical studies for some of the new investigational pediatric circulatory support devices.

EXPANDING VAD SUPPORT TO CHALLENGING PEDIATRIC POPULATIONS

Single-Ventricle Anatomy and Ventricular Assist Device Support

Improvement in preoperative, perioperative, and postoperative management of patients with congenital heart disease (CHD) has resulted in dramatic increase in long-term survival. Life expectancy for children with most types of congenital heart lesions is comparable to the general population; however, there is a subset of CHD—namely single ventricle anatomy—in which long-term mortality and morbidity into adulthood remains unacceptably high. This growing population of failed single ventricle palliations will benefit from effective mechanical support as a bridge to transplantation or even destination therapy; however, to date this endeavor has been disappointing, with higher mortality and morbidity reported in a variety of single-center experiences. The unnatural history of Fontan (total cavopulmonary connection) circulation is that of progressive systemic venous congestion with the sequelae of protein-losing enteropathy, renal, hepatic and intestinal congestion. The pathways of deterioration can vary and include systemic systolic ventricular dysfunction with low cardiac output and elevated left atrial pressures or diastolic ventricular dysfunction with elevated ventricular end-diastolic pressures resulting in elevated Fontan pressures. Pure systolic ventricular dysfunction can be managed successfully with implantation of a VAD. In situation of diastolic dysfunction or restrictive physiology in addition to decreased systolic function, a continuous-flow pump may be superior by providing continuous unloading of the pulmonary venous system.

Options to unload the systemic venous system in failed Fontan circulation include (1) revision of the Fontan pathway with creation of a larger systemic venous capacitance chamber and insertion of cannula to an extracorporeal device (Berlin Heart EXCOR or centrifugal pump), or (2) takedown of the Fontan back to Glenn (bidirectional cavopulmonary anastomosis) and implantation of systemic VAD. This last option provides better unloading of the infradiaphragmatic circulation, at the cost of lower oxygen saturations and risk of paradoxical emboli. There is also the possibility that a systemic VAD in patients with preserved systolic function but elevated end-diastolic pressures and consequently pulmonary venous congestion may be beneficial in lowering left atrial pressures and alleviating symptoms of Fontan failure. Even a marginal decrease in left atrial pressures may be sufficient to decrease Fontan pressures and improve systemic venous congestion. As device technology improves—with lower adverse event profile and better compatibility with activities of daily living—VADs may soon prove to be adjunctive therapy in

protein-losing enteropathy refractory to maximal medical therapy.

Posttransplant Graft Failure and Ventricular Assist Device Support

Cardiac graft failure can manifest either early (<30 days) or late after transplantation because of variable causes. Current strategies to increase the donor pool—including the use of marginal donors²⁸ and desensitization with human leukocyte antigen-incompatible donor²⁸—may be increasing the risk of posttransplant graft failure.

ECMO has been the mainstay of MCS strategies for graft dysfunction, providing complete respiratory and cardiac support, allowing for recovery or preservation of end-organ function. However, ECMO is limited in its duration of support to weeks and fraught with bleeding, thrombotic, and infectious complications that increase exponentially over time. As such, intermediate to long-term MCS strategies have been attempted with guarded success. The challenges of MCS in graft failure are multifaceted and include redo sternotomy, increased risk of infection and poor wound healing in the setting of continued immunosuppression, progressive biventricular dysfunction with polyvalvar involvement, and arrhythmia. Thus, standard LVAD support is generally not successful, with most patients requiring biventricular support. As such, many believe that total extraction of the graft with implantation of a total artificial heart, the Syncardia TAH (Syncardia Systems, Inc., Tucson, AZ), may be an advantageous support strategy, as it obviates the need for continued immunosuppression. Currently, the TAH is not applicable for use in most children, as the two 70-cc pneumatically driven pumps for right and left heart support require a minimum anterior-posterior chest diameter of 10 cm at the level of thoracic vertebra 10 (T10) to fit. However, a 50-cc Syncardia TAH pump has been developed with a lower size range of 1 m² BSA which may have a wider applicability to the pediatric population.

Destination Ventricular Assist Device Therapy in Children

Destination therapy (DT) is the use of a VAD as a primary therapeutic option when heart transplantation is contraindicated or not desired. The landmark Randomized Evaluation of Mechanical Assistance in the Treatment of Congestive Heart Failure (REMATCH) trial in adults demonstrated that the implantation of LVADs for DT was superior to standard medical therapy in patients with end-stage heart failure who were not eligible for transplantation.³² Now, more than a decade after this trial, the use of VADs as DT in adults is an accepted therapy to improve quality of life.^{33,34}

Based on the success of DT in adults, it is not surprising that this indication is now being more widely considered for children. However, the ability to offer DT remains restricted to children who are large enough to use the currently available intracorporeal devices suitable for outpatient care. Patient selection for this type of therapy will be of paramount importance, and likely an

evolving process. Children who may benefit from DT include those with Duchenne muscular dystrophy with cardiomyopathy, chemotoxicity induced cardiomyopathy with ongoing malignancy or unlikely long-term remission, complex palliated CHD with multiple comorbidities, retransplant graft dysfunction in the setting of noncompliance, and cardiac dysfunction in the setting of neurological impairment or uncertain neurodevelopmental outcomes. There have been reported cases of LVAD implantation for Duchenne Muscular Dystrophy (MD),³⁵ and it is expected that this will continue to grow because of strong advocacy by the patients and their families.

Pediatric DT programs are now emerging in North America. DT VAD programs mandate the integrated services of an extensive and dedicated multidisciplinary team, with heavy involvement of psychology, social work, occupational and physiotherapy, in addition to nursing and medical support. Perhaps the most important aspect of DT is outlining the expectations of what VAD therapy may offer the patients and their families prior to device implantation. Ultimately, the goal of DT is not only to prolong life, but to improve the quality of life for the patient and family. The use of VADs for DT in children will continue to evolve as device technology improves, narrowing the gap between quality of life and survival outcomes for VADs and heart transplantation. Commensurate with the advancement in device technology, we, as a field in pediatric advanced cardiac support, will need to keep pace with the ethical implications and clinical challenges of altering the natural history of life limiting conditions by acknowledging the benefits and critically evaluating the consequences.

LONGER-TERM OUTCOMES FROM MECHANICAL SUPPORT IN CHILDREN

Formal, prospective evaluation of the longer-term outcomes for children receiving mechanical support of the circulation has not been undertaken. Despite the successful deployment of mechanical support to enable cardiac recovery and discharge from hospital, longer-term cardiac function and the functional status of patients should be determined. In addition to cardiac status, end-organ injury and residual deficits need to be evaluated, particularly neurologic outcomes.⁴⁵ The ELSO Registry data indicate a combined neurologic complication rate of 26% in all patients receiving cardiac ECMO, with seizures being the most common neurologic event (9.5%). In a recent retrospective report of outcomes for infants supported with ECMO after cardiectomy (median follow-up, 55 months), only 50% of survivors were determined to have no motor or cognitive deficit of any sort.⁸⁹ As waiting times for cardiac transplantation increase as a result of the increasing number of potential recipients, the need for device options that can provide extended durations of support is more pressing than ever. Longer-term VAD support often allows patients to be bridged more effectively to transplantation than on continuous inotropic support. A multi-institutional retrospective analysis from the Pediatric Heart Transplant Study examined the outcomes in nearly 100 children supported with a variety of

VADs while awaiting transplantation from 1993 to 2003.⁹⁰ In the study, overall, three quarters of the children survived to transplantation—a figure that improved to 85% in the more recent era and is comparable to outcomes reported in adults. Notably, the wait-list survival with mechanical support exceeded that of patients who were supported on maximal medical therapy.

Concurrently with the Pediatric Circulatory Support initiative from the NHLBI in 2004, the National Institutes of Health also sponsored the creation of the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS). This registry is being designed to have a dedicated pediatric arm that will collect both retrospective and prospective data and will hopefully facilitate the eventual approval of pediatric devices in the United States.

As the technology and indications for mechanical support of the circulation in children continue to evolve and advance, simultaneous outcome studies will be essential to allow us to make better decisions about available mechanical support options for children.

Indications for Early Tracheal Extubation

Discharge

The management of congenital heart disease (CHD) has progressed significantly over the past three decades. Most congenital heart lesions are now amenable to anatomic or physiologic repair early in infancy. Advances in diagnostic and interventional cardiology, the evolution of surgical techniques and conduct of cardiopulmonary bypass, and refinements in postoperative management have all contributed to a substantial decrease in morbidity and mortality associated with CHD. The approach to repairing CHD as early as possible, preferably in the neonatal period, has had significant implications for the anesthetic care of these critically ill infants during cardiac surgery. To meet this challenge, a clear understanding of neonatal respiratory and cardiac physiology, neonatal responses to anesthesia and surgery, and the pathophysiology of complex congenital heart defects is necessary.

PATHOPHYSIOLOGY

Care of the critically ill neonate requires an appreciation of the special structural and functional features of immature organs. The neonate appears to respond more quickly and extremely to physiologically stressful

circumstances; this can be expressed in terms of rapid changes in, for example, pH, lactic acid, glucose, and temperature.¹

The physiology of the preterm and full-term neonate is characterized by a high metabolic rate and O₂ demand (a twofold to threefold increase compared with adults), which may be compromised at times of stress because of limited cardiac and respiratory reserve. The myocardium in the neonate is immature, with only 30% of the myocardial mass being composed of contractile tissue, compared with 60% in mature myocardium. In addition, neonates have a lower velocity of shortening, a diminished length-tension relationship, and a reduced ability to respond to afterload stress.^{2,3} Because the compliance of the myocardium is reduced, the stroke volume is relatively fixed and cardiac output is heart rate dependent; therefore, the Frank-Starling relationship is functional only within a narrow range of left ventricular end-diastolic pressure. The cytoplasmic reticulum and T-tubular system are underdeveloped, and the neonatal heart is dependent on the trans-sarcolemmal flux of extracellular calcium both to initiate and sustain contraction.

Cardiorespiratory interactions are important in neonates and infants. In simple terms, *ventricular*

interdependence refers to a relative increase in ventricular end-diastolic volume and pressure, causing a shift of the ventricular septum and diminished diastolic compliance of the opposing ventricle.⁴ This effect is particularly prominent in the immature myocardium. Therefore, a volume load from an intracardiac shunt or valve regurgitation, and a pressure load from ventricular outflow obstruction or increased vascular resistance, could lead to biventricular dysfunction. For example, in neonates with tetralogy of Fallot and severe outflow obstruction, hypertrophy of the ventricular septum can contribute to diastolic dysfunction of the left ventricle and an increase in end-diastolic pressure. This does not improve immediately after repair in the neonate, as it takes some weeks or months for the myocardium to remodel; therefore, an elevated left atrial pressure is not an unexpected finding after neonatal tetralogy repair. This circumstance can be exacerbated further if there is a persistent volume load to the left ventricle after surgery, such as from residual ventricle septal defects (VSDs).

The mechanical disadvantage of an increased chest wall compliance and reliance on the diaphragm as the main muscle of respiration limits ventilatory capacity in the neonate. The diaphragm and intercostal muscles have fewer type I muscle fibers (i.e., slow-contracting, high oxidative fibers for sustained activity), and this contributes to early fatigue when the work of breathing is increased. In the newborn, only 25% of fibers in the diaphragm are type I, reaching a mature proportion of 55% by 8 to 9 months of age.^{5,6} Diaphragmatic function can be compromised significantly by raised intra-abdominal pressure, such as from gastric distention, hepatic congestion, or ascites.

The tidal volume of full-term neonates is 6 to 8 mL/kg and, because of the mechanical limitations just mentioned, minute ventilation is respiratory-rate dependent. The resting respiratory rate of the newborn infant is between 30 and 40 breaths per minute, which provides the optimal alveolar ventilation to overcome the work of breathing and match the compliance and resistance of the respiratory system. When the work of breathing increases, such as with parenchymal lung disease, airway obstruction, cardiac failure, or increased pulmonary blood flow, a larger proportion of total energy expenditure is required to maintain adequate ventilation. Infants therefore fatigue readily and fail to thrive.

The neonate has a reduced functional residual capacity (FRC) secondary to an increased chest wall compliance (FRC being determined by the balance between chest wall and lung compliance). Closing capacity is also increased in newborns, with airway closure occurring during normal tidal ventilation.⁷ Oxygen reserve is therefore reduced, and in conjunction with an increased basal metabolic rate and oxygen consumption two to three times adult levels, neonates and infants are at risk for hypoxemia. However, atelectasis and hypoxemia do not occur in the normal neonate because FRC is maintained by dynamic factors, including tachypnea, breath stacking (early inspiration), expiratory breaking (expiratory flow interrupted before zero flow occurs), and laryngeal breaking (auto-positive end-expiratory pressure [PEEP]).

Organ immaturity of the liver and kidney may be associated with reduced protein synthesis and glomerular filtration, such that drug metabolism is altered and synthetic function is reduced. These problems can be compounded by the normally increased total body water of the neonate compared with the older patient, along with the propensity of the neonatal capillary system to leak fluid out of the intravascular space.⁸ This is especially pronounced in the neonatal lung, in which the pulmonary vascular bed is almost fully recruited at rest and the lymphatic recruitment required to handle increased mean capillary pressures associated with increases in pulmonary blood flow may be unavailable.⁹

The caloric requirement for neonates, especially preterm neonates, is high (100 to 150 kcal/kg per 24 hr) because of metabolic demand. The task of supplying nutrition for growth becomes even more difficult when necessary limits are placed on the total amount of fluid that may be administered parentally or by the enteral route. Hyperosmolar feedings have been associated with an increased risk for necrotizing enterocolitis in the preterm neonate, or to the neonate born at term who has decreased splanchnic blood flow of any cause (e.g., left-sided obstructive lesions).^{10,11}

PHYSIOLOGIC APPROACH TO CONGENITAL HEART DISEASE

Specific classification of congenital heart defects is difficult because of the complex nature of many lesions. Basing identification and classification on physiology brings an organized framework to the intraoperative anesthetic management and postoperative care of children with complex CHD.

Single Ventricle Physiology

Single ventricle physiology is used to describe the situation wherein complete mixing of pulmonary venous and systemic venous blood occurs at the atrial or ventricular level and the ventricles then distribute output to both the systemic and pulmonary beds. Because of this physiology:

- Ventricular output is the sum of pulmonary blood flow (Qp) and systemic blood flow (Qs).
- Distribution of systemic and pulmonary blood flow is dependent on the relative resistances to flow (both intra- and extra-cardiac) into the two parallel circuits.
- Oxygen saturations are the same in the aorta and the pulmonary artery.

This physiology can exist in patients with one well-developed ventricle and one hypoplastic ventricle and in patients with two well-formed ventricles.

In the case of a single anatomic ventricle, there is always obstruction to either pulmonary or systemic blood flow because of complete or near complete obstruction to inflow and/or outflow from the hypoplastic ventricle. In this circumstance, there must be a source of both systemic and pulmonary blood flow to assure postnatal survival. In some instances of a single anatomic ventricle,

a direct connection between the aorta and the pulmonary artery via a patent ductus arteriosus (PDA) is the sole source of systemic blood flow (hypoplastic left heart syndrome) or of pulmonary blood flow (pulmonary atresia with intact ventricular septum); this is known as *ductal dependent circulation*. In other instances of a single anatomic ventricle, intracardiac pathways provide both systemic and pulmonary blood flow without the necessity of a PDA. This is the case in tricuspid atresia with normally related great vessels, a nonrestrictive VSD, and minimal or absent pulmonary stenosis.

Single ventricle physiology can exist in the presence of two well-formed anatomic ventricles when there is complete or near complete obstruction to outflow from one on the ventricles:

- Tetralogy of Fallot (TOF) with pulmonary atresia (PA) where pulmonary blood flow is supplied via a PDA or multiple aortopulmonary collateral arteries (MAPCA)
- Truncus arteriosus
- Severe neonatal aortic stenosis and interrupted aortic arch (in both lesions a substantial portion of systemic blood flow is supplied via a PDA)
- Heterotaxy syndrome, in which there are components of systemic venous (superior vena cava, inferior vena cava, hepatic veins, azygous veins) and pulmonary venous return to both right and left sided atria, and in which atrial morphology is ambiguous

With single ventricle physiology, the arterial saturation (SaO_2) will be determined by the relative volumes and saturations of pulmonary venous and systemic venous blood flows that have mixed and reach the aorta. This is summarized in the following equation:

$$\text{Aortic saturation} = \frac{[(\text{Systemic venous saturation}) \times (\text{Total systemic venous blood flow}) + (\text{Pulmonary venous saturation}) \times (\text{Total pulmonary venous blood flow})]}{(\text{Total systemic venous blood flow} + \text{Total pulmonary venous blood flow})}$$

A typical example is as follows:

$$\text{SaO}_2 = [(65)(3.3) + (98)(2.8)] / (3.3 + 2.8) = 80\%$$

Intercirculatory Mixing

Intercirculatory mixing is the unique situation that exists in transposition of the great vessels, in which two parallel circulations exist because of the existence of atrioventricular concordance (RA-RV, LA-LV) and ventriculoarterial discordance (RV-Ao, LV-PA). This produces a parallel rather than a normal series circulation. In this arrangement, blood flow will consist of parallel recirculation of pulmonary venous blood in the pulmonary circuit and systemic venous blood in the systemic circuit. Therefore, the physiologic shunt or the percentage of venous blood from one system that recirculates in the arterial outflow of the same system is 100% for both circuits. Unless there are one or more communications (atrial septal defect [ASD], PFO, VSD, PDA) between the

parallel circuits to allow intercirculatory mixing, this lesion is incompatible with life.

An anatomic right-to-left (R-L) shunt is necessary to provide effective pulmonary blood flow, whereas an anatomic left-to-right (L-R) shunt is necessary to provide effective systemic blood flow. Effective pulmonary blood flow, effective systemic blood flow, and the volume of intercirculatory mixing must always be equal. Total systemic blood flow is the sum of recirculated systemic venous blood plus effective systemic blood flow. Likewise, total pulmonary blood flow is the sum of recirculated pulmonary venous blood plus effective pulmonary blood flow. Recirculated blood composes the largest portion of total pulmonary and total systemic blood flow, with effective blood flows contributing only a small portion of the total flows. This is particularly true in the pulmonary circuit in which the total pulmonary blood flow (Q_p) and the volume of the pulmonary circuit (LA-LV-PA) is twofold to threefold greater than the total systemic blood flow (Q_s) and the volume of the systemic circuit (RA-RV-Ao). The net result is transposition physiology, wherein the pulmonary artery oxygen saturation is greater than the aortic oxygen saturation.

Arterial saturation (SaO_2) will be determined by the relative volumes and saturations of the recirculated systemic and effective systemic venous blood flows reaching the aorta. This is summarized in the following equation:

$$\text{Aortic saturation} = \frac{[(\text{Systemic venous saturation}) \times (\text{Recirculated systemic venous blood flow}) + (\text{Pulmonary venous saturation}) \times (\text{Effective systemic venous blood flow})]}{(\text{Total systemic venous blood flow})}$$

A typical example is as follows:

$$\text{SaO}_2 = [(50)(1.2) + (99)(1.1)] / 2.3 = 73\%$$

Simple Shunts

Shunting is the process whereby venous return into one circulatory system is recirculated through the arterial outflow of the same circulatory system. Flow of blood from the systemic venous atrium or right atrium to the aorta produces recirculation of systemic venous blood. Flow of blood from the pulmonary venous atrium or left atrium to the pulmonary artery produces recirculation of pulmonary venous blood. Recirculation of blood produces a physiologic shunt. Recirculation of pulmonary venous blood produces a physiologic L-R, whereas recirculation of systemic venous blood produces a physiologic R-L shunt. A physiologic R-L or L-R shunt commonly is the result of an anatomic R-L or L-R shunt. In an anatomic shunt, blood moves from one circulatory system to the other via a communication at the level of the cardiac chambers or great vessels. Physiologic shunts can exist in the absence of an anatomic shunt. Transposition physiology is the primary example of this process.

Effective blood flow is the quantity of venous blood from one circulatory system reaching the arterial system of the other circulatory system. Effective pulmonary

blood flow is the volume of systemic venous blood reaching the pulmonary circulation, whereas effective systemic blood flow is the volume of pulmonary venous blood reaching the systemic circulation. Effective pulmonary blood flow and effective systemic blood flows are the flows necessary to maintain life. Effective pulmonary blood flow and effective systemic blood flow are always equal, no matter how complex the lesions. Effective blood flow usually is the result of a normal pathway through the heart, but it can occur as the result of an anatomic R-L or L-R shunt.

Total pulmonary blood flow (Qp) is the sum of effective pulmonary blood flow and recirculated pulmonary blood flow. Total systemic blood flow (Qs) is the sum of effective systemic blood flow and recirculated systemic blood flow. Total pulmonary blood flow and total systemic blood flow do not have to be equal. Therefore, it is best to think of recirculated flow (physiologic shunt flow) as the extra, non-effective flow superimposed on the nutritive effective blood flow.

Shunts causing an increase in pulmonary blood flow may be simple or complex, occurring among the ventricles, atria, or great arteries, and they are described by the ratio of pulmonary blood flow (Qp) to systemic blood flow (Qs), or Qp/Qs. Patients may be acyanotic or cyanotic, have one or two ventricles, or have a single outflow trunk, yet have a significant increase in Qp/Qs and be at risk for congestive heart failure (CHF) and pulmonary hypertension (Table 110-1).

In patients with large L-R shunts and low pulmonary vascular resistance, a substantial increase in pulmonary blood flow can occur. If the increase in pulmonary blood flow and pressure continues, structural changes occur in the pulmonary vasculature until eventually pulmonary

vascular resistance (PVR) becomes persistently elevated.^{12,13} The time course for developing pulmonary vascular obstructive disease depends on the amount of shunting, but changes with some lesions may be evident by 4 to 6 months of age. The progression is more rapid when both the volume and pressure load to the pulmonary circulation is increased, such as with a large VSD. As PVR decreases in the first few months after birth and the hematocrit falls to its lowest physiologic value, the increased L-R shunt, and therefore volume load on the systemic ventricle, can lead to congestive cardiac failure and failure to thrive.

The end-diastolic volume is increased in patients with an increased Qp/Qs ratio, but the time course over which irreversible ventricular dysfunction develops is variable. Generally, if surgical intervention to correct the volume overload is undertaken within the first 2 years of life, residual dysfunction is uncommon.¹⁴

The volume load on the systemic ventricle and increased end-diastolic pressure contribute to increased lung water and pulmonary edema by increasing pulmonary venous and lymphatic pressures. Compliance of the lung is therefore decreased, and airway resistance increased secondary to small airway compression by distended vessels.¹⁵⁻¹⁷ Lungs may feel stiff on hand ventilation and deflate slowly. Besides cardiomegaly on the chest radiograph, the lung fields are usually hyperinflated. Ventilation-perfusion mismatch contributes to an increased alveolar-arterial oxygen gradient, and dead-space ventilation.¹⁸ Minute ventilation is therefore increased, primarily by an increase in respiratory rate. Pulmonary artery and left atrial enlargement may compress main-stem bronchi, causing lobar collapse. Symptoms and signs of CHF to note in neonates and infants are shown in Box 110-1.

Manipulating PVR is an important means of limiting pulmonary blood flow and pressure. During anesthesia, PVR can be maintained or increased by using a low fraction of inspired oxygen (FiO₂) and altering ventilation to achieve a normal pH and PaCO₂.¹⁹ Care must be taken at induction of anesthesia, because patients may have a

TABLE 110-1 Simple Shunts: Defects and Surgical Procedures Contributing to an Increased Ratio of Pulmonary Blood Flow (Qp) to Systemic Blood Flow (Qs)

Type of Shunt	Acyanotic	Cyanotic
Two ventricles	ASD VSD CAVC DORV	D-TGA/VSD PA/VSD
Single ventricle	—	TA ± TGA HLHS DORV/MA Norwood/Sano procedure BT shunt PA/MAPCA
Aortopulmonary (AP) connection	PDA Truncus arteriosus AP window	

AP, Aortopulmonary; ASD, atrial septal defect; BT, Blalock-Taussig; CAVC, complete atrioventricular canal; DORV, double-outlet right ventricle; D-TGA, dextro-transposition of the great arteries; HLHS, hypoplastic left heart syndrome; MA, mitral atresia; MAPCA, multiple aortopulmonary collateral arteries; PA, pulmonary atresia; PDA, patent ductus arteriosus; TA, tricuspid atresia; TGA, transposition of the great arteries; VSD, ventral septal defect.

BOX 110-1 Symptoms and Signs of Cardiac Failure in a Neonate or Infant

POOR GROWTH

- Poor feeding
- Diaphoresis

INCREASED WORK OF BREATHING

- Tachypnea
- Grunting
- Flaring of ala nasi
- Chest wall retraction

DECREASED CARDIAC OUTPUT

- Tachycardia
- Gallop rhythm
- Cardiomegaly
- Poor extremity perfusion
- Hepatomegaly

diminished contractile reserve. Preload, contractility, and heart rate must be maintained; afterload reduction is often well tolerated and will reduce pulmonary flow and myocardial work.

Complex Shunts

In complex shunts, there is additional pulmonary or systemic outflow obstruction, and the Qp/Qs ratio is determined by the size of the orifice, the outflow gradient, and the resistance across the pulmonary or systemic vascular bed. The obstruction may be fixed as with valvular stenosis, or dynamic as in forms of TOF.

Outflow Obstruction

Severe outflow obstruction in the newborn may be associated with ventricular hypertrophy and vessel hypoplasia distal to the level of obstruction. The increased pressure load can cause ventricular failure, with mixing or shunting at the atrial or ventricular level (or both) necessary to maintain cardiac output if there is complete outflow obstruction. Maintenance of preload, afterload, and normal sinus rhythm is important to prevent a fall in cardiac output or coronary hypoperfusion. As the time to develop significant ventricular dysfunction is longer in patients with a chronic pressure load than in those with a chronic volume load, symptoms of CHF are uncommon unless the obstruction is severe and prolonged.

Pulmonary Hypertension

Pulmonary hypertension may be idiopathic. Patients with CHD typically have pulmonary hypertension secondary to increased pulmonary artery flow and pressure, pulmonary venous obstruction, or left atrial hypertension from systemic ventricular atrioventricular valve dysfunction or ventricular systolic or diastolic dysfunction. Factors that increase PVR and pulmonary pressures include light anesthesia with a poorly attenuated stress response, hypoxemia, hypoventilation with a fall in FRC and respiratory acidosis, metabolic acidosis, hypothermia, prolonged bypass with associated inflammatory response and capillary leak, and administration of protamine or blood products (e.g., platelets; [Box 110-2](#)).

After repair of defects with large L-R shunts, pulmonary artery pressures may remain elevated immediately after bypass, as the pulmonary arteries initially remain reactive to factors that increase PVR. While the patient is on bypass, factors contributing to this elevated pressure include compression and atelectasis of the lung, and pulmonary edema from inadequate venting of the left atrium or from the humoral and cellular response to bypass. Attenuation of the stress response with deep anesthesia using high-dose narcotics will prevent increases in PVR.²⁰ A high FiO₂ and hyperventilation to induce a respiratory alkalosis will reduce PVR, and boluses of bicarbonate may be necessary to maintain metabolic alkalosis.²¹⁻²³ Ideally, the pH should be approximately 7.45 to 7.50 and the arterial CO₂ should be 30 to 35 mm Hg. A strategy of hyperventilation to induce a respiratory alkalosis and lower PVR may have an adverse effect on central nervous

BOX 110-2 Causes of Abnormally Elevated Pulmonary Artery Pressure

- Left-to-right shunt lesion (e.g., large ventricular septal defect or patent ductus arteriosus)
- Pulmonary arteriolar smooth muscle hypertrophy (e.g., pulmonary vascular obstructive disease)
- Increased pulmonary venous pressure
- Mechanical obstruction of the pulmonary circulation
- Anatomic defects (e.g., pulmonary vein or branch pulmonary artery stenosis)
- Pulmonary embolus
- Raised intrathoracic pressure
- Lung hyperinflation
- Lung hypoinflation and hypoplasia
- Decreased alveolar oxygen tension
- Acidemia (respiratory or metabolic)
- Inflammatory response to cardiopulmonary bypass
- Drugs: protamine
- Hyperviscosity (from polycythemia)
- Blood product administration (platelets)
- Artifactual (e.g., monitoring problems, catheter malposition)

system recovery by lowering cerebral blood flow. The pattern of ventilation and maintenance of lung volumes is important: atelectasis and decreases in lung compliance can cause a significant rise in PVR and pulmonary pressures. Changes in ventilation must be made cautiously and reassessed frequently.

Several intravenous vasodilators, including the nitric oxide (NO) donors nitroprusside and glycerol trinitrate, the phosphodiesterase inhibitor milrinone, the eicosanoids prostaglandin E₁ and prostaglandin I₂,²⁴ tolazoline, and isoproterenol have been used to treat postoperative patients with elevated PVR.²⁵⁻²⁷ The chief limitation of these pharmacologic agents is that their vasodilatory effects are not specific to the pulmonary vasculature; therefore, vasodilation of the systemic vasculature and systemic hypotension may accompany reduction of pulmonary hypertension.

Inhaled NO selectively dilates smooth muscle cells in small pulmonary vessels and lowers PVR.²⁸ The selective effect of inhaled NO on the pulmonary vasculature is a result of the rapid uptake and inactivation by hemoglobin as NO diffuses from alveoli to the lumen of lung capillaries. The usefulness of inhaled NO for patients with congenital heart disease and pulmonary hypertension has been documented in several populations.^{29,30} After surgery, NO has been shown to reduce pulmonary artery pressure and PVR in patients with pulmonary venous obstruction, such as total anomalous pulmonary venous connection and mitral stenosis, to a lesser extent in patients with a large preexisting L-R shunt, and in those with cavopulmonary connections (Fontan physiology)³¹ or pulmonary hypertensive crises related to cardiopulmonary bypass (CPB). NO has also improved both pulmonary hypertension and impaired gas exchange in patients who have undergone lung transplantation. Patients with a variety of other pulmonary vascular or parenchymal diseases, including persistent pulmonary hypertension of the newborn,³²⁻³⁴ primary pulmonary hypertension, acute

respiratory distress syndrome,³⁵ and acute chest syndrome in sickle cell disease³⁶ have also shown significant improvements in oxygenation from treatment with inhaled NO.

Recent therapeutic advances have significantly improved the prognosis for patients with pulmonary arterial hypertension.^{24,37,38} The role of newer pulmonary vasodilating drugs such as the phosphodiesterase type V inhibitor sildenafil, and endothelin I blocking drugs, such as bosentan, have shown encouraging results.³⁹⁻⁴² The value of these drugs in children with CHD is yet to be established.

PREOPERATIVE EVALUATION

Patients with complex defects require frequent evaluation and often repeated cardiac operations as a staged approach to surgical repair. Previous anesthetic, bypass, or surgical problems should be noted. In general, providing continuity of care in these patients, such as by a dedicated cardiac anesthesia service, is useful to ensure consistent management practices, and it enhances the long-term relationship with patients and families.

Failure to thrive is an important indicator of cardiopulmonary compromise. Symptoms as described in [Box 110-1](#) should be noted. Murmurs and extra heart sounds may be difficult to interpret if tachycardic, but a palpable thrill usually indicates a significant murmur. Failure to thrive, lethargy, and poor exercise tolerance are significant symptoms in older children. Orthopnea, syncope, and palpitations may also be described. Recurrent respiratory infections and wheezing are common in patients with L-R shunts. Four-limb blood pressures should be compared, and room air baseline peripheral arterial saturations should be noted along with potential airway problems. The chest radiograph should be analyzed for cardiomegaly, pulmonary congestion, airway compression, and atelectasis. Echocardiographic assessment and cardiac catheterization results provide valuable information about anatomic structure, myocardial function, intracardiac pressures, shunting, and gradients across obstructions. They should be interpreted in conjunction with the cardiologist and surgeon. Patients with cardiac failure are often stabilized on digoxin, diuretics, and oral vasodilators such as captopril. Preoperative digoxin levels and hypokalemia must be checked.

The consequences of chronic hypoxemia also need special consideration. Polycythemia increases oxygen-carrying capacity, but when the hematocrit rises to greater than 65%, the increased blood viscosity causes stasis and potential thrombosis, and it exacerbates tissue hypoxia. Dehydration must be avoided, and intravenous (IV) maintenance fluids should be begun while the patient is fasting preoperatively. Bleeding disturbances, common in cyanotic patients,⁴³ can result from thrombocytopenia, defective platelet aggregation, or clotting factor abnormalities.

MONITORING

The monitoring technique used for a patient should depend on the child's condition and the magnitude of the

planned procedure. For elective patients, noninvasive monitoring (electrocardiography, pulse oximetry, capnography, and a noninvasive blood pressure cuff) is placed before induction of anesthesia.

Monitoring by electrocardiogram (ECG) is essential, because significant rhythm disturbances can occur before and after bypass, particularly with VSD and outflow tract surgery. Myocardial ischemia occurs in pediatric patients mostly because of anatomic and shunt-related problems rather than coronary occlusive disease. Anomalous coronary arteries are associated with a number of complex defects, such as transposition of the great vessels and pulmonary atresia. Ischemia also occurs when coronary perfusion pressure falls, such as in hypoplastic left heart syndrome, truncus arteriosus, and critical aortic stenosis. Ventricular fibrillation can occur in these settings,⁴⁴ particularly on induction of anesthesia. Ischemia after bypass can result from air embolism or complications related to surgery, such as coronary reimplantation or coronary compression from conduits.

Pulse oximetry is an important monitor before and after bypass, as peripheral arterial saturation levels provide an indicator of pulmonary blood flow. The anesthesiologist needs to know the patient's baseline, prebypass peripheral O₂ saturation (SpO₂), and the anticipated level after surgery. Causes for lower than expected SpO₂, in patients with single-ventricle physiology, include pulmonary venous desaturation and intrapulmonary shunt, reduced pulmonary blood flow, and low cardiac output. For patients who have undergone a two-ventricle repair, a lower than expected SpO₂ is usually secondary to intrapulmonary shunting, because of parenchymal lung disease (e.g., atelectasis, edema) or restrictive pulmonary defects (e.g., pleural effusion, pneumothorax). After repair of a neonatal right ventricular outflow tract, such as TOF or truncus arteriosus, a small atrial communication is an advantage as it provides a R-L atrial shunt. Although these patients may be cyanotic immediately after surgery, the R-L shunt will decrease and the SpO₂ will rise as the compliance of the right ventricle improves.

Once the patient is anesthetized, a direct arterial line is placed percutaneously or through a cutdown. The site of the arterial line placement needs careful consideration. For example, patients undergoing placement of a modified Blalock-Taussig shunt from the subclavian or innominate artery should have the radial arterial line placed in the opposite extremity. Similarly, a right radial arterial line is necessary when repair of coarctation of the aorta is planned. The arch anatomy and possible aberrant arterial vessels are additional considerations when planning arterial access. Aortic root pressure monitoring may be necessary immediately after bypass if the peripheral arterial pressure is damped from hypothermia or low output state. Alternatively, a femoral artery catheter may provide a more reliable arterial waveform after CPB, particularly in newborns and infants, and it is often preferable to a peripheral arterial catheter. Care must be taken to prevent thrombus and distal limb ischemia, and femoral lines are best removed early once the patient is in stable condition. Caution is necessary when flushing arterial catheters in neonates and infants, because retrograde flow into the carotid arteries is possible.⁴⁵

Some centers routinely use central venous pressure monitoring for all cardiovascular surgery. Percutaneous central venous access enables titration of volume replacement and administration of vasoactive infusions before CPB, and during CPB it may provide a measure of the adequacy of cerebral venous drainage. Insertion of central venous catheters can be particularly difficult in pediatric patients, and central venous lines should be used with caution in neonates and infants because of the risk for infection and superior vena cava thrombosis, which can have significant sequelae if collateral veins are poorly developed. Transthoracic right and left atrial lines can be inserted by the surgeon for hemodynamic pressure monitoring and drug infusions after bypass.⁴⁶ They have a low complication rate. In addition, they can be left in situ for longer during postoperative recovery and then easily removed in the intensive care unit (ICU). Swan-Ganz catheters are rarely used in pediatric cardiac surgery because of anatomic limitations. Direct pulmonary artery catheters can be inserted by the surgeon to measure pulmonary saturations, to detect residual outflow tract gradients, and for thermodilution measurement of cardiac output. Oximetric catheters can be placed percutaneously for continuous measurement of mixed venous oxygen saturation (SvO₂) in the superior vena cava.⁴⁷

Ultrasound-guided technique has been shown to increase the overall success rate and reduce the incidence of traumatic complications associated with central venous cannulation.^{48,49} The anatomy of the central venous drainage should be known before attempting percutaneous cannulation. Heterotaxy syndrome and possible vein occlusions after previous catheterization are considerations, and if in doubt, ultrasound evaluation of the position and size of a central vein before cannulation is useful.

Neurologic Monitoring

Long-term neurodevelopmental impairment is common in newborns and infants undergoing repair for complex CHD. The etiologies of adverse neurologic sequelae in these patients are multifactorial and include prenatal, preoperative, intraoperative, and postoperative factors. Cerebral protection is a concern during bypass for congenital heart surgery, particularly if deep hypothermic arrest or low-flow bypass is used, and the importance of routine perioperative monitoring of the brain is increasingly recognized. Tympanic or nasopharyngeal temperature monitoring is used to assess the adequacy of cerebral cooling and rewarming. Continuous electroencephalographic monitoring,⁵⁰ transcranial Doppler,⁵¹ and frontal lobe near-infrared spectroscopy⁵²⁻⁵⁵ or cerebral oximetry can be used to evaluate cerebral blood flow velocity and perfusion, and O₂ delivery and extraction.

Intraoperative Echocardiography

Intraoperative transesophageal echocardiography (TEE) has achieved a role in intraoperative monitoring of patients undergoing repair of CHD.⁵⁶⁻⁵⁸ The development of smaller probes has allowed transesophageal monitoring to replace epicardial echocardiographic imaging in many cases, and it is performed routinely. Placement of a

transesophageal probe after the induction of anesthesia in the operating room enables reevaluation of the anatomy before surgical intervention, but, more importantly, the adequacy of surgical repair can be evaluated as soon as the patient is weaned from CPB. Interference of the probe with the airway and the effect on unstable hemodynamics before and after CPB must be evaluated carefully to avoid the complications of this monitoring.

ANESTHESIA

Risks of Anesthesia for Children with Congenital Heart Disease

The frequency of anesthesia-related cardiac arrests during general pediatric procedures has been reported to be between 1.4 and 4.6 per 10,000 anesthesia events, which is higher than that reported in adults. An American Society of Anesthesiologists (ASA) Physical Status of greater than 3 and younger age are risk factors for cardiac arrest during pediatric anesthesia, and a recent study demonstrated that patients with CHD are also at increased risk for cardiac arrest during cardiac surgery.⁵⁹ The incidence of anesthesia-related and procedure-related cardiac arrests was highest in neonates, and although it can be difficult to distinguish contributing factors in patients with underlying cardiac disease, there is a possible association between altered coronary perfusion and myocardial ischemia and cardiac arrest. Coronary perfusion can be reduced in patients who have uncontrolled or continuous runoff of blood flow from the systemic to pulmonary circulation, and therefore low aortic root diastolic pressure (e.g., patients with a diagnosis of truncus arteriosus, and patients with a ductus-dependent systemic circulation such as hypoplastic left heart syndrome and interruption of the aortic arch or coarctation with VSD). Patients with altered coronary blood flow, such as those with pulmonary atresia, an intact ventricular septum, and a right ventricle-dependent coronary circulation from fistulas, are also at increased risk for ischemia. These patients also have a limited ability to increase coronary blood flow when myocardial oxygen demand is increased, such as occurs secondary to tachycardia, increased contractility, or wall stress in response to a surgical stimulus if there is an inadequate depth of anesthesia to blunt a stress response.^{20,44,60} The importance of maintaining diastolic pressure and coronary perfusion is also important in the setting of severe left ventricle hypertrophy (e.g., Williams syndrome, hypertrophic cardiomyopathy).⁶¹

Induction of Anesthesia

Because of the potential for rapid and dramatic hemodynamic changes in young patients with CHD, especially infants, the complete preparation of anesthetic and monitoring equipment and required drugs is essential. Adequate assistance should be immediately available during the induction of anesthesia in case problems develop.

The choice of induction technique is influenced by the response to premedications, the parent-child-anesthesiologist relationship, and the anesthetic management

plan. In older patients who have minimal compromise of their cardiac reserve, the choice of induction techniques is large. Inhalation, intravenous, or intramuscular induction of anesthesia can be accomplished provided individual pathophysiologic limitations are understood. Cooperative children with an adequate cardiac reserve and difficult intravenous (IV) access or a morbid fear of needles can have anesthesia induced cautiously with inhaled anesthetics, even if the patients are cyanotic. An inhalation induction with sevoflurane is suitable for most infants and children, provided they have stable ventricular function and adequate hemodynamic reserve. This emphasizes the importance of preoperative evaluation when planning the induction technique. Inhalational induction can be used safely in patients with cyanotic heart disease, although uptake may be slower because of the R-L shunt.⁶² Saturations will generally increase, provided cardiac output is maintained and airway obstruction is avoided.

An IV induction should be used for all patients with severely limited hemodynamic reserve, particularly those with severe ventricular failure or pulmonary hypertension. When hemodynamic instability during induction is likely, starting an inotropic agent such as dobutamine or dopamine before induction should be considered. Although the stress of placing an IV line may be considerable for some patients, particularly those with difficult IV access after previous procedures, the IV line is preferable to the potential myocardial depression during an inhalation induction.

A combination of fentanyl (15 to 25 µg/kg) and rocuronium (1.0 mg/kg) provides hemodynamic stability and prompt airway control, and it attenuates the stress-induced increase in PVR associated with intubation. IV ketamine (1 to 3 mg/kg) is safe and reliable, providing hemodynamic stability and minimal increases in PVR. It is particularly useful in patients with severe CHF and ventricular outflow tract obstructions. Atropine (20 µg/kg) or glycopyrrolate (10 µg/kg) is traditionally given concurrently because of increased secretions. If IV access is difficult and stressful in infants, a combination 4 mg/kg of ketamine, 10 µg/kg of glycopyrrolate, and 2 mg/kg of suxamethonium intramuscularly allows prompt induction and airway control.

Etomidate is an anesthetic induction agent with minimal cardiovascular and respiratory depression,⁶³ and it is frequently used to induce anesthesia in patients with limited hemodynamic reserve. An IV dosage of 0.1 to 0.3 mg/kg induces rapid loss of consciousness with a duration of action of 3 to 5 minutes. Etomidate can be used as an alternative to the synthetic opioids for induction of anesthesia in patients with limited myocardial reserve.

Barbiturates and propofol can be used in patients with normal ventricular function. The principal hemodynamic effect of propofol in children with CHD is a decrease in systemic vascular resistance (SVR) and direct myocardial depression. In children with an intracardiac L-R shunt, this can result in changes in the Qp/Qs ratio, and it can lead to a low cardiac output state.⁶⁴ Patients with a R-L intracardiac shunt may experience a faster induction and loss of consciousness, and the dosage must be carefully

titrated to effect in these circumstances. Titrated dosages are suitable for short procedures, such as cardioversion or TEE. Midazolam (0.1 to 0.2 mg/kg) is also a useful adjunct during a narcotic induction, but it can cause hypotension in patients dependent on a high sympathetic drive.

Maintenance of Anesthesia

Anesthesia maintenance techniques depend on the patient's preoperative cardiorespiratory status, the pathophysiology of the underlying cardiac defect, the surgical procedure, the conduct of CPB, potential postoperative surgical problems, and the anticipated postoperative management. Once induction of anesthesia and control of the airway are accomplished and monitoring is adequate, anesthesia can be maintained with inhaled anesthetics or additional IV drugs as dictated by the response of each patient, intraoperative events, and postoperative plans.

Stress responses to pain and other noxious stimuli are profound in even the youngest neonates, regardless of postconception age.^{1,65} These hormonal and metabolic stress responses can be deleterious,⁶⁶ particularly in patients with marginal hemodynamic reserve. High-dose narcotic techniques provide hemodynamic stability and are commonly used to maintain anesthesia, with the choice of agent and dosage dependent on the planned procedure, the duration of bypass, and the anticipated postoperative management. Patients with good cardiac function undergoing relatively short bypass procedures, such as ASD closure, can be extubated in the operating room or soon after surgery. Fentanyl (10 to 20 µg/kg) in combination with isoflurane or sevoflurane is suitable before bypass. During CPB, awareness is a potential problem. Methods to prevent this vary, but isoflurane (1%) can be continued on the bypass machine or doses of midazolam might be given intermittently. After bypass, inhalational agents are titrated as required according to hemodynamic responses.

Stress Response

In general terms, the stress response is a systemic reaction to injury, with hemodynamic, endocrinologic, and immunologic effects (Box 110-3). Stress and adverse postoperative outcome have been closely linked in critically ill newborns and infants, which is not surprising because of the precarious balance of limited metabolic reserve and increased resting metabolic rate. Metabolic derangements, such as altered glucose homeostasis, metabolic acidosis, salt and water retention, and a catabolic state contributing to protein breakdown and lipolysis, are commonly seen in sick neonates and infants after major stress.⁶⁷ This complex of maladaptive processes may be associated with prolonged mechanical ventilation and ICU stay, as well as increased morbidity and mortality.

The neuroendocrine stress response is activated by afferent neuronal impulses from the site of injury, traveling via sensory nerves through the dorsal root of the spinal cord to the medulla and hypothalamus. Anesthesia can therefore have a substantial modulating effect on the

BOX 110-3 Systemic Response to Injury**AUTONOMIC NERVOUS SYSTEM ACTIVATION**

- Catechol release
- Hypertension, tachycardia, vasoconstriction

- Acute phase reaction
- Granulocytosis

ACTH, Adrenocorticotrophic hormone.

neuroendocrine pathways of the stress response by virtue of providing analgesia and loss of consciousness.

It is important to distinguish between suppression of the endocrine response and attenuation of hemodynamic responses to stress. Because of their direct effects on the myocardium and vascular tone, anesthetic agents can readily suppress the hemodynamic side effects of the endocrine stress response. The same is true when inotropic and vasoactive agents are administered during anesthesia. However, the postoperative consequences of the endocrine stress response—in particular, fluid retention and increased catabolism—remain unabated. Relying on hemodynamic variables to assess the level of stress is therefore often inaccurate. Metabolic indices such as hyperglycemia and hyperlactatemia are also indirect markers of stress, particularly as they are influenced by other factors such as fluid administration and cardiac output.

The effect of surgical stress has been particularly evaluated in neonates and infants undergoing cardiac surgery.^{66,68,69} A conclusion from these studies supported the notion that reducing the stress response with large-dose opioid anesthesia, and extending this into the immediate postoperative period, was important to reduce the morbidity and mortality associated with congenital heart surgery in neonates.

However, these studies were performed over a decade ago, and during the intervening period, there have been substantial changes in the perioperative management of children with heart disease as well as the management of cardiopulmonary bypass in general. With these changes, outcomes have improved considerably. In the early experience of bypass in neonates and infants, the use of high-dose opioid anesthesia to modulate the stress response was perceived to be one of the few clinical strategies available that was associated with demonstrable

improvement in morbidity and mortality.⁶⁸ More recently, it has been demonstrated that opioids do not in fact modify the endocrine or metabolic stress response initiated by CPB; despite this, mortality and morbidity continue to remain low.

Although the neonate may be more labile to changes in intravascular pressures, PVR, and cardiac output than older children, in fact the neonate is highly capable of coping with the acute phase of surgical stress. It is less common nowadays to see neonates in the immediate post-bypass period with extensive peripheral edema or anasarca and, along with that, impaired ventricular function, reactive pulmonary hypertension, and substantial alterations in lung compliance and airway resistance. One example is the incidence of postoperative pulmonary hypertensive events. Pulmonary hypertensive crisis was more common a decade or more ago in infants who had been exposed to weeks or months of high pulmonary pressure and flow, such as truncus arteriosus, complete atrioventricular canal defects, and transposition of the great arteries with ventricular septal defects. High-dose opioids were an important component of management for patients at risk for pulmonary hypertensive crises, but this occurs much less frequently nowadays when patients undergo an operation at an earlier age and are therefore less likely to have significant or irreversible changes in the pulmonary vascular bed. Therefore, changes in surgical practice, and in particular the timing of surgery, have meant that the longer-term pathophysiologic consequences of various defects are less apparent than they were 10 to 20 years ago. A strategy of high-dose opioid anesthesia to blunt the stress response may therefore be a less critical determinant of outcome.

This is not to say, however, that high-dose synthetic opioids are not necessary for neonatal cardiac surgery. Synthetic opioids are potent analgesics and provide hemodynamic stability because of their lack of negative inotropic or vasoactive properties. Because of the limited physiologic reserve, the pathophysiology of underlying cardiac defects, and the clinical consequences of the systemic inflammatory response to bypass in the neonates, using an anesthetic technique that has minimal hemodynamic side effects is clearly desirable.

The main aim is to provide an anesthetic that maintains hemodynamic stability and allows the anesthesia team to concentrate on all other aspects of the surgery, bypass, and post-CPB care. Sudden changes in hemodynamics before and after bypass may develop secondary to myocardial dysfunction, residual anatomic lesions, loss of sinus rhythm, changes in preload state, variable pulmonary vascular resistance, and alterations in mechanical ventilation, to mention a few. Using a high-dose opioid anesthesia technique allows the anesthesiologist to focus on an evolving hemodynamic picture without the distraction of side effects from anesthetic drugs.

DISCONTINUATION OF CARDIOPULMONARY BYPASS

The effects of prolonged CPB are in part related to the interactions of blood components with the extracorporeal

circuit, which cause a systemic inflammatory response. This is magnified in children because of the large bypass circuit surface area and priming volume relative to patient blood volume. The clinical consequences include increased interstitial fluid and generalized capillary leak, and potential multiorgan dysfunction. Total lung water is increased with an associated decrease in lung compliance and increase in the alveolar–arterial oxygen gradient. Myocardial edema results in impaired ventricular systolic and diastolic function. A secondary fall in cardiac output by 20% to 30% is common in neonates in the first 6 to 12 hours after surgery, contributing to decreased renal function and oliguria.⁷⁰ Sternal closure may need to be delayed because of mediastinal edema and associated cardiorespiratory compromise when closure is attempted. Ascites, hepatic congestion, and bowel edema may affect mechanical ventilation, cause a prolonged ileus, and delay feeding. A coagulopathy after CPB can contribute to delayed hemostasis.

An organized approach must be taken to weaning a patient from CPB so that a smooth transition is ensured. There should be communication between the surgeon and the anesthesiologist regarding anticipated difficulties. Blood volume is assessed by direct visualization of the heart and by monitoring right or left atrial filling pressures. When filling pressures are adequate, the patient is fully warmed, acid–base status is normalized, heart rate is adequate, adequate minute ventilation is established, and sinus rhythm is achieved, the drainage from the venous cannula is retarded, flow is reduced gradually, and the patient is weaned from CPB. The need for vasopressor and inotropic support during weaning from bypass is determined by close observation of the heart during the rewarming phase.

Optimal ventricular filling pressures are estimated by referring to filling pressures from preoperative catheterization data, the appearance of the heart, and infusion of small increments of volume while watching filling and systemic arterial pressures. The direct measurement of oxygen saturations from chambers of the heart enables calculations of a residual intracardiac shunt immediately after surgery, and direct pressure measurements across systemic and pulmonary outflow tracts enables detection of significant residual obstruction. TEE can be used to evaluate ventricular function and to assess surgical repair.

After discontinuing bypass, and despite full rewarming on bypass, rebound mild hypothermia often develops in neonates and infants. Active measures to decrease radiant and evaporative losses are necessary because of the increased metabolic stress, pulmonary vasoreactivity, coagulopathy, and potential for dysrhythmias associated with hypothermia. However, hyperthermia must also be actively avoided because of the associated increase in metabolic rate and the potential for ongoing neurologic injury, particularly when myocardial function may be depressed and cerebral autoregulation impaired.⁷¹

Hemostasis may be difficult to obtain if bypass has been prolonged and if there are extensive, high-pressure (often concealed) suture lines. Prompt management and meticulous control of surgical bleeding is essential to prevent the complications associated with a massive

transfusion. Besides hemodilution of coagulation factors and platelets, complex surgery with long bypass times increases endothelial injury and exposure to the non-endothelialized surface of the pump circuit, thereby stimulating the intrinsic pathway, and thus platelet activation and aggregation. Early transfusion of platelets and clotting factors, either as cryoprecipitate or fresh-frozen plasma, is recommended. Pharmacologic approaches to reduce bleeding and transfusion in cardiac surgical patients include the use of lysine analogue antifibrinolytics, which have been demonstrated to reduce blood loss and transfusion requirements after cardiac surgery.⁷² The optimal doses and target plasma level of these agents have not been established, but typically aminocaproic acid is administered as a 75-mg/kg bolus to the patient, a 75-mg/kg bolus to the CPB pump prime, and a continuous infusion of 75 mg/kg/hr. Recently it was suggested that low plasma levels (20 µg/mL) of tranexamic acid would be obtained for children between 5 and 40 kg with a 6.4-mg/kg bolus followed by a continuous infusion of 2.0 to 3.1 mg/kg/hr (larger infusion rate in smaller patients).⁷³ At Boston Children's Hospital, we typically administer a 100-mg/kg bolus to the patient, a 100-mg/kg bolus to the CPB pump prime, and a continuous infusion of 10 mg/kg/hr in neonates, infants, and children weighing less than 20 kg.

The serine protease inhibitor aprotinin was effective⁷⁴ but it has been withdrawn from clinical use because of concerns for possible increase in mortality and end-organ damage after cardiac surgery in the adult.^{75–78} Recombinant factor VIIa seems to effectively and immediately reduce excessive or life-threatening nonsurgical bleeding that is unresponsive to standard hemostatic therapy, but caution is required because of an increased risk for thromboembolic complications, such as graft occlusion, stroke, and myocardial infarction.^{79–81} In addition, administration of rFVIIa should not halt efforts to find and remedy all sources of medical and surgical bleeding.

POSTOPERATIVE MANAGEMENT

The optimal postoperative management of patients with CHD requires a multidisciplinary approach, with a thorough understanding of the precise anatomic diagnosis, pathophysiology, and details of the surgical and CPB technique. For most patients, postoperative recovery is uncomplicated, and, in general, when the patient's clinical progress or postoperative cardiorespiratory function does not follow the expected course, myocardial function must be evaluated and possible residual defects must be investigated with echocardiography, cardiac catheterization, or both.

Analgesia

The assessment of adequate analgesia in children can be difficult, particularly when they are paralyzed and ventilated. Primarily, autonomic signs such as hypertension, tachycardia, pupillary size, and diaphoresis are used. If not paralyzed, children will grimace and withdraw from a painful stimulus, and if they are breathing

spontaneously, changes in respiratory pattern may be evident, such as tachypnea, grunting, and splinting of the chest wall.

However, changes in autonomic signs reflect not only pain. Other causes include awareness as patients emerge from anesthesia and sedation, fever, hypoxemia, hypercapnia, changes in vasoactive drug infusions, and seizures. If not diagnosed correctly, patients may receive additional opioid or benzodiazepine doses when hypertensive and tachycardic, which will only contribute to tolerance and possible withdrawal symptoms later.

Sedatives

Chloral hydrate is commonly used to sedate children before medical procedures and imaging studies.⁸² It can be administered orally or rectally in a dose ranging from 25 to 50 mg/kg (maximum dosage, 1 g), with an onset of action within 15 to 30 minutes and a duration of action 2 to 4 hours. Chloral hydrate should be used to promote intermittent sedation in the ICU and not be prescribed as a repetitive scheduled medication.⁸³ Administered intermittently, it can be used to supplement benzodiazepines and opioids, it can assist sedation during drug withdrawal, and it is useful as a nocturnal hypnotic when trying to establish normal sleep cycles.

Benzodiazepines are the most commonly used sedatives in the ICU because of their anxiolytic, hypnotic, and amnesic properties. Although they provide excellent conscious sedation, they can cause dose-dependent respiratory depression and result in significant hypotension in patients with limited hemodynamic reserve. After long-term administration, tolerance and withdrawal symptoms are common.

Opioid analgesics are the mainstay of pain management in the ICU. They can also provide sedation for patients who require mechanical ventilation and for blunt hemodynamic responses to procedures such as endotracheal tube suctioning. Intermittent dosing of opioids can provide effective analgesia and sedation after surgery, although periods of oversedation and undermedication can occur because of peaks and troughs in drug levels. A continuous infusion is therefore advantageous.

Morphine, in intermittent IV doses of 0.05 to 0.1 mg/kg or as a continuous infusion at 50 to 100 µg/kg/hr, provides excellent postoperative analgesia for most patients. The sedative property of morphine is an advantage over the synthetic opioids; however, histamine release can cause systemic vasodilation and an increase in pulmonary artery pressure.

The synthetic opioids fentanyl, sufentanil, and alfentanil have a shorter duration of action than morphine and do not cause histamine release; therefore, they produce less vasodilation and hypotension. Fentanyl is commonly prescribed after cardiac surgery. It blocks the stress response in a dose-related fashion while maintaining both systemic and pulmonary hemodynamic stability.^{20,84} Chest wall rigidity is an idiosyncratic and dosage-related reaction that can occur with a rapid bolus in newborns and older children. A continuous infusion of fentanyl (5 to 10 µg/kg/hr) provides analgesia after surgery, although it often needs to be combined with a benzodiazepine to

maintain sedation. High variability between children exists in fentanyl clearance, making titration of an infusion difficult. The experience with extracorporeal membrane oxygenation indicates that tolerance to and dependence on a fentanyl infusion develops rapidly, and significant increases in infusion rate may be required.

The development of tolerance is dose and time related, and it is a particular problem after cardiac surgery in patients who received a high-dose opioid technique to maintain anesthesia. Physical dependence with withdrawal symptoms (e.g., dysphoria, fussiness, crying, agitation, tachypnea, tachycardia, diaphoresis, feeding intolerance) may be seen in children and can be managed by gradually tapering the opioid dosage or administering a longer-acting opioid, such as methadone. Methadone has a potency similar to that of morphine, with the advantage of a prolonged elimination half-life of 18 to 24 hours. It can be administered IV and is absorbed well orally.

Alternative methods of opioid delivery that are often effective after cardiac surgery include patient-controlled analgesia and epidural opioids, as a bolus or by continuous infusion. Patients receiving epidural opioids must be monitored closely for potential respiratory depression, and side effects include pruritus, nausea, vomiting, and urinary retention.

Newer agents such as dexmedetomidine (an α_2 -adrenergic agonist) are being used increasingly for sedation and analgesia in pediatric patients because of their favorable sedative and anxiolytic properties combined with their limited effect on respiratory function. Dexmedetomidine is used during general anesthesia or for conscious sedation, and for sedation in the critical care unit, and it also has a potential role in preventing emergence delirium and helping with narcotic withdrawal.⁸⁵ Because of its adverse cardiovascular effects, including hypotension and bradycardia, it should be used with caution in children with CHD.⁸⁶

In children who are difficult to sedate, and in those who have often received significant doses of opioids or benzodiazepines for sedation, a low-dose infusion of propofol (30 to 100 µg/mg/min) can be used. It is not approved for sedation in children in the intensive care setting, but it can be highly effective for a short period (up to 6 to 8 hours) to assist with weaning from mechanical ventilation and, in effect, with detoxification from previous sedatives to which they have become tolerant. Because of potential hemodynamic complications, propofol must be used with caution in patients with limited hemodynamic reserve, and the dosage and duration of use must be strictly limited because of the potential yet rare complication of propofol infusion syndrome.⁸⁷

Assessment of Cardiac Output

A complete evaluation of cardiac output (CO) should be the initial focus of management in the ICU after cardiac surgery. Low CO is associated with longer duration of mechanical ventilatory support, ICU stay, and hospital stay, all of which can increase the risk for morbidity or mortality. Data from physical examination, routine laboratory testing, and bedside hemodynamic monitoring are all considered during the initial assessment.

Postoperative patients with low CO can exhibit a variety of abnormalities on physical examination or on bedside monitoring and laboratory values (Table 110-2). The mechanisms underlying low CO in a specific patient can be related to a number of factors, including residual or unrecognized anatomic cardiovascular defects, type of surgical procedure (e.g., right ventricular [RV] dysfunction after right ventriculotomy), surgical complications (e.g., compromised coronary artery perfusion), dysrhythmia (supraventricular or ventricular) or loss of atrioventricular conduction, low preload (ongoing bleeding), high afterload (e.g., systemic vasoconstriction related to CPB), metabolic derangement (e.g., hypocalcemia, hypomagnesemia), and pulmonary hypertension (primarily affecting RV function).

In neonates and infants, a fall in CO of approximately 30% within 9 to 12 hours after surgery can be anticipated even when the surgical repair is excellent. This pattern is best documented for neonates with d-transposition of the great arteries,⁷⁰ but it also occurs in neonates undergoing complete repair of TOF or truncus arteriosus. Pharmacologic support of the myocardium may be necessary and anticipated to mitigate the effects of decreased cardiac

index in these patients, including an increase in inotropic support with dopamine or the use of drugs such as milrinone to lower afterload.

Strategies for treating the patient with a low CO state should focus on optimizing the balance between oxygen delivery and demand. In a low CO state, oxygen and metabolic demand should be minimized by maintaining an adequate depth of analgesia and sedation, including chemical paralysis to avoid movement and reduce muscle tone and oxygen debt. Strict avoidance of hyperthermia from any cause is essential, and in some circumstances mild hypothermia may be preferable, although the effect of peripheral vasoconstriction and increase in SVR could have an adverse effect on myocardial wall stress and oxygen requirement.

Oxygen delivery can be increased by optimizing O₂ content (hemoglobin and FiO₂) and by a combination of the factors contributing to CO (i.e., contractility, preload, afterload, and heart rate). Because decreased myocardial contractility occurs frequently after reparative or palliative surgery with CPB, pharmacologic enhancement of contractility is used commonly in the ICU. Before initiating treatment with an inotrope, the volume status, serum ionized Ca²⁺ level, and cardiac rhythm should be evaluated. Dopamine is often the initial treatment for hypotension; it increases contractility by elevating intracellular Ca²⁺, from direct binding to myocyte β_1 -adrenoceptors, and by increasing norepinephrine levels. At a dose of greater than 5 $\mu\text{g/kg/min}$, dopamine should be infused through a central venous catheter to avoid superficial tissue damage should extravasation occur. The dose is titrated to achieve the desired systemic blood pressure, although some patients, especially older children and adults, may develop an undesirable dose-dependent tachycardia. Dobutamine may be less effective than dopamine as a single agent in the treatment of moderate hypotension because it reduces SVR.⁸⁸

If a patient does not respond adequately to dopamine (up to 10 $\mu\text{g/kg/min}$) and has persistent signs of a low CO state, including poor extremity perfusion, hypotension (>30% decrease in mean arterial blood pressure for age), tachycardia, elevated atrial filling pressure, oliguria, and lactic acidemia, treatment with epinephrine should be considered. Epinephrine can be added to dopamine at a starting dose of 0.05 to 0.1 $\mu\text{g/kg/min}$, with subsequent titration of the infusion to achieve the target systemic blood pressure. At high doses (i.e., $\geq 0.5 \mu\text{g/kg/min}$), epinephrine can produce significant renal and peripheral vasoconstriction plus significant tachycardia, and those who require persistent doses of epinephrine greater than 0.3 to 0.5 $\mu\text{g/kg/min}$ should be evaluated for the possibility of mechanical circulatory support. Norepinephrine at doses of 0.01 to 0.2 $\mu\text{g/kg/min}$ can also be considered in patients with severe hypotension and low SVR (e.g., “warm” or “distributive” shock), inadequate coronary artery perfusion, or inadequate pulmonary blood flow with a systemic-to-pulmonary artery shunt. A combination of low-dose epinephrine (e.g., <0.1 $\mu\text{g/kg/min}$) or dopamine with an IV afterload-reducing agent such as milrinone is frequently beneficial to support patients with significant ventricular dysfunction accompanied by elevated afterload. There can be a decrease in

TABLE 110-2 Manifestations of Low Cardiac Output after Cardiac Surgery

By Examination

Core hyperthermia
Tachycardia or bradycardia
Hypotension (for age and weight)
Narrow pulse pressure
Decreased peripheral perfusion
Hepatomegaly
Ascites
Oliguria

By Monitoring

Arterial waveform Blunted or dampened upstroke
Narrow pulse pressure
RAp or CVP, LAP Low intravascular fluid status
(decreased) Inadequate preload
RAp or CVP, LAP Poor ventricular function
(increased) Residual volume load
Residual outflow tract obstruction
Ischemia
Loss of normal sinus rhythm
Atrioventricular valve regurgitation/
stenosis
Tamponade

By Laboratory and Radiographic Results

SVO₂ Decreased with an increased
arteriovenous O₂ difference
(>25%-30%)
Acid-base balance Metabolic acidosis with increased
anion gap
Increased arterial lactate
Elevated blood urea nitrogen and
creatinine
Increased liver transaminases

Pulmonary edema
Pleural effusion

CVP, Central venous pressure; LAP, left atrial pressure;
RAp, right atrial pressure.

responsiveness to increasing dosages of catecholamines over time, and vasopressin, at a dose of 10 to 120 mU/kg/hr, is a potent vasopressor, which could help to improve the hemodynamics in advanced shock without compromising cardiac function.⁸⁹

Patients with the clinical features of relative adrenal insufficiency can benefit from stress steroid therapy. This insufficiency is primarily a clinical finding of poor vascular tone with persistent hypotension and volume requirement, refractory to increasing inotrope and vasopressor support. The serum cortisol level may be low or show a limited response to adrenocorticotrophic hormone stimulation testing, but the ranges of normal have not been established for pediatric patients, in particular for newborns and infants after cardiac surgery, and there is no consistent correlation between serum cortisol level and low cardiac output state. Nevertheless, stress doses of hydrocortisone (50 mg/m²/day) have been demonstrated to increase systemic blood pressure and lower inotrope scores, although they have not been definitively demonstrated to improve eventual survival.⁹⁰⁻⁹² The increased risk for infection and poor wound healing dictates that stress dosing of steroids should be for a brief period (3 to 5 days) rather than continuing with a long taper.

Hypothyroidism is another cause for persistent low cardiac output state after cardiac surgery. Triiodothyronine (T₃) levels have been demonstrated to be low after CPB, and they may remain low for up to 48 hours after surgery, particularly if a sick euthyroid state develops and there is decreased conversion of thyroxine to the active T₃ in peripheral tissues. An infusion of T₃ at a dose of 0.05 µg/kg/hr has been shown to improve blood pressure and a composite score of recovery after cardiac surgery in newborns and infants.^{93,94}

If the rhythm cannot be determined with certainty from a surface 12- or 15-lead ECG, then temporary epicardial atrial pacing wires, if present, can be used with the limb leads to generate an atrial ECG.⁹⁵ Temporary epicardial atrial or ventricular pacing wires (or both) are routinely placed in most patients to allow mechanical pacing should sinus node dysfunction or heart block occur in the early postoperative period. Because atrial wires are applied directly to the atrial epicardium, the electrical signal generated by atrial depolarization is significantly larger and thus easier to distinguish than the P wave on a surface ECG. Sinus tachycardia, which is common and often secondary to medications (e.g., sympathomimetics), pain and anxiety, or diminished ventricular function, must be distinguished from a supraventricular, ventricular, or junctional tachycardia. Heart block can diminish cardiac output by producing either bradycardia or loss of atrioventricular synchrony, or both. Complete heart block may be transient in approximately a third of cases, but if it persists beyond postoperative day 9 or 10, it is unlikely to resolve, and a permanent pacemaker is indicated.⁹⁶

Elevated afterload in both the pulmonary and systemic circulations frequently follows surgery with CPB.⁹⁷ An increase in systemic afterload from elevated SVR may significantly increase myocardial work and reduce end-organ perfusion. Treatment of elevated SVR includes recognizing and improving conditions that exacerbate

vasoconstriction (e.g., pain and hypothermia) and administering a vasodilating agent such as a phosphodiesterase inhibitor milrinone or a NO donor (e.g., nitroprusside).⁹⁸⁻¹⁰²

Fluid Management

Fluid management in the immediate postoperative period is critical because of the inflammatory response to CPB and significant increase in total body water that often occurs. Capillary leak and interstitial fluid accumulation continue after surgery in neonates and infants, often necessitating ongoing volume replacement. A fall in cardiac output and increased antidiuretic hormone secretion contribute to delayed water clearance and potential pre-renal dysfunction. An elevated CVP will result in elevated renal venous pressure, further compromising renal perfusion particularly in the setting of diminished arterial blood pressure. During bypass, optimizing the circuit prime hematocrit and oncotic pressure, attenuating the inflammatory response with steroids, and using modified ultrafiltration techniques may help to limit interstitial fluid accumulation.¹⁰³⁻¹⁰⁵ During the first 24 hours after surgery, maintenance fluids should be restricted to 50% of full maintenance, and volume replacement should be titrated to appropriate filling pressures and hemodynamic response.

Oliguria in the first 24 hours after complex surgery and CPB is common. Cardiac output should be enhanced, with volume replacement and vasoactive drug infusions if necessary, before diuretics can be effective. In addition, low-dose dopamine (3 µg/kg/min) has the advantage of redistributing renal blood flow to promote diuresis. Fenoldopam mesylate, a selective dopamine (DA₁) receptor agonist that causes smooth muscle relaxation, leading to both renal and splanchnic vasodilation, has been used to provide renal protection during periods of ischemia and hypoxia such as during hypothermic CPB.¹⁰⁶ At a dose of 0.1 to 0.5 µg/kg/min, it may also have a role in postoperative ICU management to enhance renal perfusion by decreasing renal vascular resistance.¹⁰⁷ It should be recognized that fenoldopam has a hemodynamic profile similar to sodium nitroprusside and as such the advantages of selective renal vasodilation may be offset by systemic hypotension.

Furosemide (1 to 2 mg/kg IV every 8 hours) is a commonly prescribed loop diuretic that is excreted into the renal tubular system before producing diuresis; therefore, low cardiac output reduces its efficacy. Bolus dosing may result in a significant diuresis over a short period, thereby causing changes in intravascular volume and possibly hypotension. A continuous infusion of 0.2 to 0.3 mg/kg/hr after an initial IV bolus of 1 mg/kg often provides a consistent and sustained diuresis without sudden fluid shifts. Chlorothiazide (10 mg/kg IV or orally every 12 hours) is also an effective diuretic, particularly when used in conjunction with loop diuretics.

Peritoneal dialysis, hemodialysis, and continuous venovenous hemofiltration provide alternative renal replacement therapy in patients with persistent oliguria and renal failure.^{108,109} In addition to enabling water and solute clearance, nutritional support can be increased. A

peritoneal dialysis catheter can be placed into the peritoneal cavity at the completion of surgery or later in the ICU. This can be done in the ICU because of the need for renal support, to reduce intra-abdominal pressure from ascites that may be compromising mechanical ventilation, and to improve fluid management to allow administration of parenteral nutrition. Drainage may be significant in the immediate postoperative period as third-space fluid losses continue, and replacement with albumin or fresh-frozen plasma (or both) may be necessary to treat hypovolemia and hypoproteinemia. To enhance fluid excretion if oliguria persists, low-volume peritoneal dialysis may be effective, although a persistent communication between the peritoneum, mediastinum, and pleural cavities after surgery will limit the effectiveness of peritoneal dialysis and is a relative contraindication.

Pulmonary Function and Mechanical Ventilation

Altered respiratory mechanics and positive-pressure ventilation may have a significant influence on hemodynamics after congenital heart surgery. Although changes in alveolar O_2 (PAO_2), $PaCO_2$, and pH significantly affect PVR, the mean airway pressure and changes in lung volume during positive-pressure ventilation also affect PVR, preload, and ventricular afterload. Therefore, the approach to mechanical ventilation should be directed not only at achieving a desired gas exchange but also at addressing the potential cardiorespiratory interactions of positive-pressure ventilation. This is particularly critical during weaning.

Altered lung mechanics and ventilation-perfusion abnormalities are common problems in the immediate postoperative period.^{110,111} Besides preoperative problems resulting from increased Q_p/Q_s , additional considerations include the surgical incision and lung retraction, increased lung water after CPB, possible pulmonary reperfusion injury, surfactant depletion, and restrictive defects from atelectasis and pleural effusions. In general, neonates and infants, with their limited physiologic reserve, should not be weaned from mechanical ventilation until hemodynamically stable, and until factors contributing to an increase in intrapulmonary shunt and altered respiratory mechanics have improved.

An increase in mean intrathoracic pressure during positive-pressure ventilation decreases preload to both pulmonary and systemic ventricles, but it has opposing effects on afterload to the ventricles^{112,113} (i.e., it decreases afterload to the systemic ventricle but increases afterload on the pulmonary ventricle). Changes in lung volume have a major effect on PVR, which is lowest at FRC, whereas hypoinflation or hyperinflation can result in a significant increase in PVR.¹¹⁴ An increase in PVR increases the afterload or wall stress on the right ventricle, compromising RV function and contributing to decreased LV compliance secondary to interventricular septal shift. In addition to low cardiac output, signs of RV dysfunction (e.g., tricuspid regurgitation, hepatomegaly, ascites, pleural effusions) may be observed. An increase in mean intrathoracic pressure increases the afterload on

the RV from direct compression of extra-alveolar and alveolar pulmonary vessels. Patients with normal RV compliance, and without residual volume load or pressure load on the ventricle after surgery, usually show little change in RV function from the alteration in preload and afterload that occurs with positive-pressure ventilation. However, these effects can be magnified in patients with restrictive RV physiology or poor diastolic function after congenital heart surgery, especially in neonates who have required a right ventriculotomy for repair of TOF, pulmonary atresia, or truncus arteriosus, and in patients with concentric RV hypertrophy.

The systemic arteries are under higher pressure and not exposed to radial traction effects during inflation or deflation of the lungs. Therefore, changes in lung volume will affect LV preload, but the effect on afterload depends on changes in intrathoracic pressure alone rather than changes in lung volume. Wall stress is directly proportional to the transmural LV pressure—that is, to the difference between the intracavity LV pressure and surrounding intrathoracic pressure. An increase in intrathoracic pressure, as occurs during positive-pressure ventilation, therefore reduces the transmural gradient and wall stress on the left ventricle. This is one explanation for the beneficial effect of positive-pressure ventilation and PEEP in patients with LV failure.¹¹⁵ In addition, patients with LV dysfunction may have impaired pulmonary mechanics secondary to increased lung water, decreased lung compliance, and increased airway resistance. The work of breathing is increased and neonates and infants in particular can fatigue early because of limited respiratory reserve. A significant proportion of total body oxygen consumption is directed at the increased work of breathing in neonates and infants with LV dysfunction, contributing to poor feeding and failure to thrive. Therefore, positive-pressure ventilation has an additional benefit in patients with significant volume overload and systemic ventricular dysfunction by reducing the work of breathing and oxygen demand.

Weaning from positive-pressure ventilation can be difficult in patients with persistent systemic ventricular dysfunction. During spontaneous respiration, the transmural pressure across the systemic ventricle is increased, and this sudden increase in wall stress can contribute to pulmonary edema and low cardiac output state. It is therefore often beneficial to continue vasoactive support during weaning and extubation if there is concern for ventricular dysfunction.

Weaning from Mechanical Ventilation

After congenital cardiac surgery, most patients wean without difficulty if they have had no complications with repair or CPB, but some patients with borderline cardiac function and residual volume overload may require prolonged mechanical ventilation and a slower weaning process. Weaning is a dynamic process, and continued reevaluation is necessary.

The method of weaning varies among patients. Most patients can be weaned using either a volume- or pressure-limited mode by simply decreasing the intermittent mandatory ventilation rate. Guided by physical examination,

BOX 110-4 Factors Contributing to the Inability to Wean from Mechanical Ventilation after Congenital Heart Surgery

RESIDUAL CARDIAC DEFECTS

- Volume load

hemodynamic criteria, respiratory pattern, and arterial blood gas measurements, the mechanical ventilator rate is gradually reduced. Patients with limited hemodynamic and respiratory reserve may demonstrate tachypnea, diaphoresis, and shallow tidal volumes as they struggle to breathe spontaneously against the resistance of the endotracheal tube. The addition of pressure- or flow-triggered pressure support of 10 to 15 cm H₂O above PEEP is often beneficial in reducing the work of breathing.

Numerous factors contribute to the inability to wean from mechanical ventilation after congenital heart surgery (Box 110-4). In general, however, residual cardiac defects after surgery causing either a volume or pressure load must be excluded by echocardiography or cardiac catheterization if a patient fails to wean from ventilation as expected.

Indications for Early Tracheal Extubation

The heterogeneous nature of congenital cardiac defects and wide age range make it difficult to establish rigid protocols for cardiovascular and respiratory management after surgery. Each patient must be viewed individually and managed according to preoperative condition and stability, surgeon preference, any surgical or CPB-related complications, and postoperative cardiorespiratory status (Box 110-5). In keeping with the strategy of early surgical intervention and repair to promote improved longer-term growth and development, and with less emphasis on

- Analgesia management

complete suppression of the stress response in the immediate postoperative period, it is possible to move patients expeditiously through the ICU in a safe yet efficient fashion.

Patients undergoing selected non-CPB or closed cardiac surgery and thoracic procedures are usually suitable for early tracheal extubation. This includes infants and older children undergoing procedures such as patent ductus arteriosus and vascular ring ligation. Infants and older children undergoing repair of coarctation of the aorta may benefit from early extubation to avoid the hypertension and tachycardia that often accompanies a slow wean from mechanical ventilation in the ICU after surgery. The risk for rebound hypertension and need to protect high-pressure surgical suture lines often dictates early blood pressure control with vasodilating and β -blocking drugs. In addition, mild-to-moderate hypothermia is often deliberately induced during surgery in an effort to optimize spinal cord protection while the aorta is cross-clamped, and tracheal extubation should be delayed until patients are normothermic.

In our experience, neonates and infants who require surgical modification of pulmonary blood flow, either by placement of a pulmonary artery band or creation of a systemic-to-pulmonary artery shunt, are not suitable for early extubation management protocols. We routinely continue mechanical ventilation and deep sedation for at least the first postoperative night until cardiorespiratory stability is attained.

Children undergoing relatively short bypass procedures using mild-to-moderate hypothermia, such as ASD repair, small VSD closure, and right ventricle-to-pulmonary artery conduit replacement, are often suitable for weaning and extubation in the operating room or early after ICU admission. These patients generally have a stable preoperative clinical status, demonstrate few complications related to CPB, and have an uncomplicated postoperative course.¹¹⁶

Infants who are in stable clinical condition before surgery and who are undergoing a complete repair using moderate-to-deep hypothermia on CPB, such as those undergoing closure of a large VSD, complete atrioventricular canal defect, or TOF, are often suitable for early extubation in the first 6 to 12 hours after surgery, provided they have stable cardiac output, stable gas exchange, and no surgical complications such as bleeding. Nevertheless, if there has been a large volume load on the ventricle before surgery or a labile pulmonary vascular resistance secondary to increased pulmonary blood flow, cautious management should be guided by hemodynamic and respiratory function as patients begin to emerge from sedation.

Infants and older children undergoing some types of LV outflow tract repair, including subaortic stenosis repair with the Konno operation or subaortic membrane resection, and aortic valvuloplasty or replacement, usually have well-preserved and often hyperdynamic ventricular systolic function. Hypertension and tachycardia are frequently a management concern in these patients in the immediate postoperative period. Not only will these factors increase the risk for disruption of suture lines, but the increased myocardial work can contribute to ischemia and increase the likelihood for ventricular tachyarrhythmias. This is especially a concern during emergence from anesthesia and sedation. Provided ventricular function is stable, hemostasis has been secured, and there are no concerns for ventricular tachyarrhythmias, it is often preferable for these patients to be extubated early after surgery (6 to 12 hours), rather than undergoing a more prolonged weaning process. The combination of esmolol and sodium nitroprusside is useful for controlling blood and reflex increases in contractility in patients with increased LV mass following procedures to relieve LVOTO. This combination prevents the development of tachycardia and diastolic hypotension that potentially compromises subendocardial perfusion in patients with LVH.

After creation of a cavopulmonary connection, such as a bidirectional Glenn shunt or a modified Fontan procedure, patients usually benefit from early tracheal extubation. Effective pulmonary blood flow is enhanced during spontaneous ventilation because of the lower mean intrathoracic pressure, but despite this goal, these patients should be weaned only after hemodynamic stability is achieved. After a bidirectional Glenn procedure, it is usually possible to extubate the trachea within 12 hours after surgery.

After the modified Fontan procedure, patients can also typically be weaned and extubated within 12 hours of surgery. In the current surgical era of almost routine fenestration of the right atrial baffle, the arterial oxygen saturation should be in the range of 80% to 90% after

surgery. Provided the patient is well perfused, has a transpulmonary gradient of 5 to 10 mm Hg, does not have an acidosis or persistent large volume requirement, transfer from the ICU within 2 to 3 days of surgery can be accomplished.

The response to surgery and bypass can vary considerably between neonates and is often unpredictable. At Boston Children's Hospital, neonates undergoing two-ventricle repairs are usually managed with sedation or paralysis, or both, in the immediate postoperative period until hemodynamic and respiratory stability has been attained, although there are clear differences depending on diagnosis and procedure. For example, after procedures such as an uncomplicated arterial switch operation for d-transposition of the great arteries, or repair of an interrupted aortic arch with VSD closure, many neonates are sufficiently stable to start to wean from mechanical ventilation and be extubated by the first or second postoperative day.

On the other hand, neonates who have undergone a right ventriculotomy, such as after neonatal repair of TOF or truncus arteriosus, commonly demonstrate restrictive RV physiology in the immediate postoperative period. A low cardiac output state with increased right-sided filling pressure may be evident, and continuing sedation and paralysis is often necessary for the first 48 to 72 hours until diastolic function improves.

Neonates undergoing a Norwood-type or a Sano procedure for hypoplastic left heart syndrome or other forms of single ventricle with aortic arch obstruction, can pose considerable management problems in the immediate postoperative period. This is one group of patients in whom sedation and paralysis should be continued initially after surgery to minimize the stress response and any imbalance between oxygen supply and demand until a stable circulation and gas exchange has been achieved. Inotrope and vasoactive support is usually required, often combined with afterload reduction to reduce myocardial work and improve systemic perfusion. Volume replacement to maintain preload is essential, and monitoring mixed venous O₂ saturation as an indicator of cardiac output is beneficial.

Discharge

The cost of intensive care medicine is high. As the mortality and morbidity associated with congenital cardiac surgery have declined, length of ICU stay, total hospital stay, and cost effectiveness have become important outcome variables. The timing of discharge from the ICU is therefore an important management decision. For the majority of patients who have a stable hemodynamic and respiratory status, the decision to transfer out of the ICU is not difficult. The function of all organ systems should be assessed and considered in this decision, although the focus will be on cardiovascular and respiratory function. In addition to poor cardiac output and residual anatomic lesions, a variety of noncardiac problems can complicate recovery and prolong ICU stay (Box 110-6). This decision should be multidisciplinary, with particular attention paid to nursing availability and experience, and the availability of adequate monitoring.

BOX 110-6 Criteria for Intensive Care Unit Discharge

CARDIOVASCULAR

- Stable blood pressure and systemic perfusion without requiring intravenous vasoactive support
- Invasive intravascular monitoring not indicated
- Stable cardiac rhythm (usually sinus) and no need for external pacing using temporary wires

RESPIRATORY

- Adequate ventilation rate and pattern, no signs of airway obstruction, and effective cough
- Appropriate oxygenation (according to physiology after surgery)
- No restrictive pulmonary defects that would limit ventilation or oxygenation, including atelectasis, pneumothorax (after chest tube removal), or pleural effusion
- Neurologic status adequate to protect airway

FLUID AND METABOLISM

- Afebrile
- Advancing on caloric requirements with stable glucose levels
- Even fluid balance with stable diuretic management
- Stable electrolyte balance with appropriate supplementation

APPROPRIATE NURSING INTENSITY

- Minimal chest physical therapy or bronchodilator treatments required
- Established nutrition plan (enteral or parenteral)
- Controlled analgesic or sedation requirements
- Appropriate nursing staff numbers according to the intensity of care

HISTORY OF INTRAOPERATIVE NEUROMONITORING

Brain injury is the most common and potentially disabling complication following congenital heart surgery. With improved survival, the focus has shifted to optimizing functional outcomes. An important goal of therapy for every congenital heart surgical patient is to reduce the risk of brain injury as much as possible. Along with updated perfusion, anesthetic, and surgical strategies, techniques for neuromonitoring have been refined and adopted by many centers performing pediatric cardiothoracic surgery.

Penfield and Boldrey first reported intraoperative neurophysiologic monitoring in 1937.¹ They used direct cortical stimulation during operations for epilepsy. Recording an electroencephalogram directly from the cerebral cortex, also for epilepsy surgery, was first done in 1949 by Jasper and Marshall and Walker.¹ Routine scalp electroencephalography (EEG), used first during carotid endarterectomy, was introduced in the late 1960s.¹ Doppler ultrasound evaluation of the extracranial cerebral arteries was first reported in 1965 by Miyazaki and Kato.² Transcranial Doppler (TCD) was reported by

Aaslid in 1982 after measuring the flow of the middle cerebral artery with a probe placed on the scalp over the temporal bone.³ Near-infrared spectroscopy (NIRS) was introduced clinically in 1985 for monitoring cerebral oxygenation in preterm infants.⁴ Spinal intraoperative monitoring, specifically somatosensory evoked potentials, was developed in the 1970s.¹ The first intraoperative neuromonitoring clinical service was established at the University of California at Los Angeles in 1979,¹ and commercial neurophysiologic monitoring equipment became available in the early 1980s.

NEURODEVELOPMENTAL OUTCOMES

Introduction

Survival after congenital heart surgery has improved, and the focus has shifted to optimizing neurodevelopmental outcomes. Survivors of repair of congenital heart disease in the neonatal period demonstrate cognitive, motor, speech, visual, and learning abnormalities.⁵

Determining causation in abnormal neurodevelopment and the occurrence of neurodevelopmental disability is a challenging endeavor. Genetic predisposition and

many other nonmodifiable patient factors, including prematurity, socioeconomic status, and maternal education, have been shown to be risk factors for worse neurodevelopmental outcomes. In addition, there is increasing evidence that congenital heart disease alters fetal brain growth and development.

In addition to nonmodifiable factors, operative management factors have been implicated in altering neurodevelopmental outcome. This includes preoperative/postoperative hypoxemia and arrest, cardiopulmonary bypass and circulatory arrest strategies, hematocrit levels during cardiopulmonary bypass, and blood gas management during bypass.

Nonmodifiable Factors Associated with Adverse Neurodevelopmental Outcomes

Fetal Brain Development and Preoperative Brain Abnormalities

Beginning in the third trimester of fetal life, patients with congenital heart disease are known to have smaller gestational age- and weight-adjusted brain volumes and impaired neuroaxonal development and metabolism.⁶ These abnormalities are most pronounced in patients with complex types of heart defects such as hypoplastic left heart syndrome and transposition of the great arteries.⁶ Structural malformations of the brain occur at a much higher rate in patients with congenital heart disease than in the general population.⁷ Microcephaly, microencephaly, and other malformations, including absence of the corpus callosum, have been documented in necropsy series of patients with hypoplastic left heart syndrome.⁸ Neonates with congenital heart disease have altered cerebral hemodynamics often with lower than normal cerebral blood flow and/or oxygen delivery. There is evidence of delayed white matter development, which can lead to an increased risk of white matter injury (periventricular leukomalacia [PVL]) and microcephaly. One study of neonates with complex congenital heart disease used preoperative pulsed arterial spin-label perfusion magnetic resonance imaging (MRI) to quantify cerebral blood flow.⁹ More than half of the cohort had developmental or acquired lesions, and the cerebral blood flow was less than half of that reported in normal, term neonates.¹⁰ The same study also examined cerebrovascular responsiveness to CO₂, and found that PVL was associated with decreased CO₂ responsiveness. Abnormal cerebrovascular reactivity to CO₂ has been associated with increased mortality and worse neurodevelopmental outcomes.^{11,12} White matter injury characterized by PVL is the most common pattern of injury.¹³ The mechanism of this injury is thought to be the result of effects of hypoxia and/or ischemia on pre-myelinating oligodendrocyte precursors during their most vulnerable time of 24 to 34 weeks gestation.¹⁴ Up to 40% of neonates with congenital heart disease have PVL on preoperative MRI, and PVL has been shown to be associated with poor neurodevelopmental outcomes.^{9,15,17} The incidence of PVL is highest in neonates undergoing cardiopulmonary bypass. A study by Galli and colleagues revealed a 54% incidence of PVL in neonates compared

to 4% in infants.¹⁸ PVL is the neurologic lesion associated with cerebral palsy in infants born prematurely.¹⁹ This pattern of brain injury is seen not only in preterm newborns but also in term neonates with congenital heart disease.²⁰ A comparison of newborns with congenital heart disease and a control cohort without heart defects revealed that almost one third of those with congenital heart disease had white matter injury.²¹ The injury pattern was not seen in those without heart defects.

Prematurity

Preterm birth, even in infants without congenital heart disease, is a powerful predictor of worse neurodevelopmental outcome. Along with low birth weight, preterm birth has been associated with long-term behavioral and learning issues. In a study of 125 very low-birth-weight preterm infants who were evaluated with the Bayley Scales of Infant and Toddler Development III at 24 months, later gestational age was associated with better neurodevelopmental outcome.²²

Socioeconomic Factors

Other nonmodifiable patient factors that adversely affect neurodevelopmental outcomes are socioeconomic status and maternal education. In a study of neurodevelopmental outcomes after repair of total anomalous pulmonary venous connection, lower socioeconomic status was predictive of lower scores on the Mental Developmental Index (MDI) of the Bayley Scales of Infant Development II.²³ The Single Ventricle Reconstruction trial is the randomized, prospective trial comparing shunt types in the Norwood procedure. Evaluation of this cohort at 14 months demonstrated that lower maternal education was associated with lower MDI scores.²⁴

Genetic Polymorphisms

Many genetic syndromes are associated with congenital heart disease, including Down syndrome,²⁵ Noonan syndrome,²⁶ Williams syndrome,²⁷ and DiGeorge syndrome (22q11.2 microdeletion).²⁸ These syndromes are associated with developmental delay, and assigning causation of neurodevelopmental delay can be challenging. For example, individuals with DiGeorge syndrome have a mean IQ in the 70s,²⁹ a predisposition to psychiatric disorders,³⁰ and an increased incidence of white matter abnormalities.³¹

There is also evidence that genetic variants that modify the brain's response to injury and subsequent recovery may also be important determinants of neurodevelopmental outcomes. The first genetic polymorphism studied in relation to congenital heart disease and operations was apolipoprotein E (APOE).⁵ APOE regulates cholesterol metabolism and is the primary lipid transport vehicle in the central nervous system; there also is evidence that APOE is important for neuronal repair.⁵ There are three APOE alleles (e2, e3, e4) on chromosome 19 that vary by a single amino acid. The Children's Hospital of Philadelphia evaluated the association of APOE genotype and

postoperative neurodevelopmental outcome at age 1 year.⁵ Neurodevelopmental outcomes were evaluated using the Bayley Scales of Infant Development II. The APOE e2 allele was associated with a significantly lower Psychomotor Developmental Index (PDI) score after adjustment for perioperative covariates, including gestational age, age at operation, sex, race, socioeconomic status, cardiac defect, and the use of circulatory arrest. Further analysis of this group revealed patient-specific factors that significantly predicted neurodevelopmental outcomes at age 1 year, including presence of genetic syndrome, low birth weight, and presence of APOE e2 allele.³³ Neurobehavioral outcomes were then evaluated in the cohort between ages 4 and 5.³⁴ Those with the APOE e2 allele had increased behavior problems, restricted behavior patterns, and impaired social skills. The entire cohort had a significantly higher proportion of patients considered either at risk for, or in the clinically significant range for, neurodevelopmental problems. The cohort was further evaluated for other genetic causes of poor neurodevelopmental outcomes beyond APOE genetic polymorphisms. A genome-wide association study identified single nucleotide polymorphisms (SNPs) associated with neurobehavioral abnormalities.³⁵ Ten SNPs reached a threshold for suggested significant associations with neurobehavioral phenotypes. These results identify additional genes—after adjusting for the effects of APOE and other genetic syndromes—that may contribute to adverse neurodevelopmental outcomes.

A study comparing the relative contribution of patient factors (gestational age, genetic syndrome, birth weight, etc.) to management factors on neurodevelopmental outcomes at 1 year of age after neonatal and infant cardiac surgery showed that patient factors explained more of the variability in the PDI (21% vs. 8%) and MDI (13% vs. 5%) than did management factors.³⁶ Factors such as gender, birth weight, and presence of genetic syndrome had a more significant impact on neurodevelopmental outcomes than did cardiopulmonary bypass time, circulatory arrest time, and hematocrit. Not all patients with congenital heart disease enter the operating room with the same neurodevelopmental prognosis. Interindividual variation of many nonmodifiable patient factors significantly contributes to widely disparate neurodevelopmental outcomes of different patients with the same cardiac diagnosis.

Management Factors Associated with Adverse Neurodevelopmental Outcomes

Many studies have examined the impact of different management strategies before and during congenital heart operations on neurodevelopmental outcomes. Operative management strategies and type of support (circulatory arrest versus low-flow cardiopulmonary bypass), pH strategy, target hematocrit value, and others have all been evaluated in relation to postoperative neurodevelopmental outcomes. Preoperative management can have a profound impact on neurodevelopmental outcomes. Acidosis, hypoxemia, hypotension, and cardiac arrest are all examples of preoperative management factors that contribute to neurodevelopmental outcomes.

Hypoxemia, Cardiac Arrest

Ductal-dependent cardiac lesions put patients at risk of acidosis, hypoxemia, and cardiovascular collapse if the diagnosis is not known and ductal closure occurs.^{8,37} The number of prenatal diagnoses of congenital heart lesions has increased in recent years. This often results in delivery in centers equipped to care for severe forms of congenital heart disease and has permitted immediate or early infusion of prostaglandin to maintain ductal patency and avoid profound acidosis and subsequent neurologic issues.³⁸⁻⁴⁰ Preoperative hypoxemia has been shown to be associated with abnormal neurodevelopmental outcomes. Neurodevelopmental testing done on a cohort of patients 5 to 10 years after repair for both cyanotic and acyanotic heart defects demonstrated more speech and language dysfunction in the group with preoperative cyanosis.⁴¹ Cardiac arrest puts all organs at risk until circulation (spontaneous or mechanical) is restored. A recent review of extracorporeal cardiopulmonary resuscitation (ECPR) survivors identified 10 studies that examined neurologic outcomes after ECPR.⁴² Overall survival of ECPR was 79%, and nine of the reports described Pediatric Cerebral Performance Category (PCPC) scores, an early test of neurologic function. Seventy-nine percent of survivors had a PCPC score of 2 or less, indicating normal or mild impairment. There are no data describing long-term neurodevelopmental outcomes after cardiac arrest and ECPR.

Many intraoperative aspects of pediatric cardiac operations have been thought to put the patient at risk for acute neurologic injury and subsequent suboptimal neurodevelopmental outcomes. As mentioned earlier, type of support (circulatory arrest versus low-flow cardiopulmonary bypass), pH strategy, and target hematocrit value have all been evaluated in relation to postoperative neurodevelopmental outcomes.

A prospective, randomized study from Boston Children's Hospital in 1988 assigned patients with transposition of the great arteries undergoing the arterial switch operation to receive either hypothermic circulatory arrest or low-flow cardiopulmonary bypass.⁴³ Neurodevelopmental outcomes (formal neurodevelopmental evaluation and MRI) for this cohort were reported at age 1 year. Patients randomized to circulatory arrest had a significantly lower mean score on the PDI of the Bayley Scales of Infant Development, and the score was inversely related to the duration of circulatory arrest. A longer duration of circulatory arrest was associated with an increased risk of neurologic abnormalities. The authors were unable to determine a safe threshold for circulatory arrest but noted that a period shorter than 35 minutes had minimal effect on the PDI score and that significant deficits were more prevalent in the group of children that had a circulatory arrest period greater than 45 minutes. At 4- and 8-year follow-up, the Boston study revealed worse motor and speech function in the circulatory arrest group.^{44,45} However, measures of behavior were worse in subjects randomized to continuous cardiopulmonary bypass. At the 16-year evaluations, most differences between the treatment groups had disappeared, but the circulatory arrest cohort scored lower on tests of executive function and visual spatial skills.⁴⁶ Both treatment groups fared worse on tests of neurodevelopment

than did population controls. Socioeconomic status explained more test variation than did treatment group assignment.

Cerebral Perfusion

A study of 57 neonates examined pre- and postoperative MRI and 1-year neurodevelopmental outcomes after receiving regional cerebral perfusion (RCP) during aortic arch reconstruction.⁴⁷ The mean RCP time was 71 minutes and the mean RCP flow was 57 mL/kg/min. New postoperative brain injury on MRI was seen in 40% of patients, which is comparable to other studies examining new postoperative MRI brain injury. The 1-year cognitive testing was at reference population norms, whereas language and motor outcomes were lower than reference population norms.

There has been increasing interest in RCP to avoid use of circulatory arrest. A study from the University of Michigan randomized 77 patients to receive either circulatory arrest or RCP during the Norwood operation.⁴⁸ They then performed neurodevelopmental testing on each cohort before the second stage operation and at age 1. The entire cohort demonstrated delayed neurodevelopment with the PDI scores being lower than the MDI scores. No statistically significant difference in MDI or PDI scores was found between the two groups, although the RCP group had lower average point estimates for both the MDI and the PDI compared with the circulatory arrest cohort.

pH strategy is an important part of the operative management of patients requiring hypothermic cardiopulmonary bypass. A recent study from the Netherlands randomized neonates to either deep hypothermic circulatory arrest or antegrade cerebral perfusion.⁴⁹ MRI was done preoperatively and 1 week postoperatively. The authors found no difference between the circulatory arrest and antegrade perfusion cohorts in terms of new cerebral injury (78% vs. 72%, respectively; $P=0.66$). The most common type of injury was white matter injury, but infarctions of the thalamus and/or basal ganglia were seen only after antegrade cerebral perfusion. Motor and cognitive testing done at 24 months showed no difference between the two groups.

Neurodevelopmental outcomes were evaluated at 4 years of age in an observational study of the impact of *APOE* genotype for an association with the use of deep hypothermic circulatory arrest.⁵⁰ No differences in unadjusted outcomes were found between those that received circulatory arrest and those that did not. However, consistent with previously published data, nonmodifiable patient factors were significantly associated with neurodevelopmental outcomes. Presence of a genetic anomaly, lower socioeconomic status and maternal education, and younger gestational age were all associated with worse outcomes.

Blood Gas Management

Two methods of blood gas management during cardiopulmonary bypass are commonly used: alpha stat and pH stat. A prospective, randomized study comparing these two strategies demonstrated an early return of

electroencephalographic activity in patients randomized to pH-stat management.⁵¹ However, neurodevelopmental testing at 1 year of age showed no benefit or detriment associated with either strategy.^{51,52}

Hematocrit

Hematocrit is a modifiable, operative management variable. It is vitally important for oxygen delivery and has been shown to affect neurodevelopmental outcomes. A prospective, randomized study done at Boston Children's Hospital assigned patients to a hypothermic bypass hematocrit of either 20% or 30%.⁵³ At 1 year, the lower hematocrit group had lower PDI scores. A second prospective, randomized study by the same group compared bypass hematocrits of 25% and 35%.⁵⁴ There were no differences between the groups on tests of neurodevelopment at 1 year of age. Based largely on these studies, most centers have chosen 25% as the lowest acceptable hematocrit while on cardiopulmonary bypass.

Glucose Management

Adult cardiac surgery literature has recently touted the benefits of tight glycemic control.⁵⁵ One study of glycemic control in a mixed (medical and surgical patients) pediatric intensive care unit compared tight glycemic control with standard management.⁵⁶ The cohort receiving tight glycemic control had a lower mortality rate but experienced high rates of hypoglycemia. Hypoglycemia is potentially dangerous to the developing brain. A more recent randomized, prospective trial enrolled 980 patients after cardiopulmonary bypass to receive either tight glycemic control or standard glucose management. No differences were found in infection rate, mortality, length of stay, or measures of organ failure. This trial had a low rate of hypoglycemia; but, with no obvious benefits, it seems unnecessary to institute tight glycemic control and risk deleterious effects on the developing brain with episodes of hypoglycemia.

INTRAOPERATIVE NEUROMONITORING

Introduction

Many institutions have adopted intraoperative neuromonitoring as a potential mechanism to minimize brain injury resulting from congenital heart surgery. It can be as simple as having the anesthesiologist monitor NIRS or as complex as using four modalities with a certified neuromonitoring professional in the operating room providing feedback during each case. The most common modalities used are NIRS, EEG, and TCD. Intraoperative NIRS is used at most congenital heart centers for all cardiopulmonary bypass cases. Somatosensory evoked potentials (SSEPs or SEPs) are used very little in congenital heart surgery and will not be discussed. [Figure 111-1](#) demonstrates the appearance of a patient after placement of multimodality neuromonitoring devices. It should be noted, however, that there is a lack of prospective, randomized data showing any benefit to intraoperative neuromonitoring.

FIGURE 111-1 ■ Intraoperative photograph demonstrating the proper placement of multimodality neuromonitoring probes. EEG, Electroencephalography; NIRS, near-infrared spectroscopy; TCD, transcranial Doppler. (Photo used with permission and courtesy of Harvey L. Edmonds, Jr., PhD.)

Near-infrared Spectroscopy

NIRS noninvasively provides an estimate of cerebral oxygen saturation because of the different absorption spectra between oxygenated and total hemoglobin. The translucency of the skull of the pediatric patient allows probes placed on the forehead to monitor the cerebral cortex. The value obtained is predominately from blood in tissue that is mostly venous blood (75% venous blood). NIRS is the only modality capable of monitoring the brain during circulatory arrest as EEG is flat and TCD will indicate no flow. Cooling and increasing levels of anesthetics will decrease metabolism and increase an individual patient's NIRS value. It is unknown what thresholds are important in the pediatric cardiac surgery patient. Some centers use parameters derived from adult studies (a decrease in NIRS below 50% and/or a drop greater than 20% from baseline) because there are no established guidelines in pediatric patients. Many centers follow trends rather than absolute numbers because there is significant interindividual variation.

Electroencephalography

Intraoperative electroencephalography is used to detect ischemia during congenital heart surgery. In normothermic patients under anesthesia, electroencephalographic slowing indicates inadequate cerebral perfusion and/or oxygenation. To monitor the EEG, cup electrodes are placed on the scalp and shaving hair is not required. Four-channel EEG (four electrodes over each hemisphere and a ground in the middle) will measure the anterior and posterior circulations of both hemispheres. Electroencephalographic recordings demonstrate significant variability between individuals, and proper analysis requires experience and skill at pattern recognition.⁵⁷ In general, patients with adequate cerebral oxygen delivery will demonstrate low-amplitude, high-frequency EEG. Ischemia is represented by high-amplitude, low-frequency waveforms.

Increasing amounts of anesthetics reliably cause diffuse slowing.⁵⁷ Slowing is usually not focal or asymmetric unless there is previous cortical injury, cortical abnormality, or new, acute injury. Fast-frequency activities are seen with lower levels of anesthetics.⁵⁷ They can be difficult to distinguish from epileptiform waves. As with slowing, focal disparities are a sign of previous injury or new, acute ischemia or injury. New epileptiform or epileptic activity indicates cortical dysfunction usually caused by ischemia. Distinguishing concerning changes from artifact can be a challenge and requires significant experience. Artifact can be caused by pulsation (near a pulsatile vessel), electrocardiogram (ECG) interference, electrical interference (such as a headlight, operating room bed, or lower extremity compression devices), or a loose electrode.⁵⁸ Comparing the EEG abnormalities to the QRS complexes on the ECG often helps resolve cases of suspected pulsation and ECG artifact.⁵⁸ Temporarily interrupting other electrical sources in the operating room can help determine if electrical interference is present.⁵⁸ Securing electrodes and checking them will help prevent artifact caused by loose electrodes.⁵⁸

There are times during a congenital heart operation with cardiopulmonary bypass that changes in the EEG can be expected.⁵⁹ Slowing in the EEG is often seen during cannulation of smaller patients. It is thought that the larger cannula-to-vessel ratio in small patients may cause obstruction to flow. In addition, a moderate amount of blood loss has a larger negative impact on circulating blood volume than in an adult. There is a transient depression in the EEG at the onset of cardiopulmonary bypass, likely caused by the relatively oxygen-deficient pump prime. Finally, hypotension after the release of the aortic crossclamp will cause EEG slowing. Deep hypothermic circulatory arrest causes slowing, and eventually flattening, of the EEG. One limitation of EEG monitoring is that the slowing seen with ischemia and/or hypoxia cannot be differentiated from that caused by anesthetics and/or cooling. The most important neuromonitoring change associated with cerebral ischemia is EEG slowing.⁵⁹ It provides continuous feedback on the function of the cerebral cortex. Combined with the other modalities, it can be used to help decide if a response to worsening neuromonitoring parameters is indicated.

Bispectral Index Scale (BIS) is another neuromonitoring tool that is used for intraoperative monitoring. The Food and Drug Administration approved it in 1996 as an EEG-based monitor of anesthetic effect.⁶⁰ BIS describes the continuous, varying signal of EEG as a number ranging from 100 (awake) to 0 (complete cortical suppression).⁶¹ It is an easy-to-use, quickly applied, one-channel processed EEG.⁶¹ In congenital heart surgery, it can be used as a marker of cortical silence when deep hypothermic circulatory arrest is used. It has also been used in conjunction with other neuromonitoring modalities to assess adequacy of cerebral perfusion.⁶²

Transcranial Doppler

TCD measures the velocity of red blood cells.⁵⁹ TCD can determine both the presence and direction of blood flow. The probe is positioned over the temporal bone and

monitors flow in the middle cerebral artery. Peak systolic velocity is a marker of cerebral inflow, and end-diastolic velocity is inversely related to cerebrovascular resistance. Inflow obstruction will result in a decrease in the peak systolic velocity. If accompanied by EEG slowing, an ischemic process is likely evolving.⁵⁹ Outflow obstruction (venous cannula malposition, for example) will increase the cerebrovascular resistance and decrease the end-diastolic velocity. High-intensity transient signals (HITSs) represent the presence of gaseous or particulate emboli within the blood vessel. Data from adult studies indicate that an increasing number of HITSs may predict postoperative neurobehavioral, pulmonary, and renal complications.⁶³ TCD is unable to differentiate between types of emboli.

Biomarkers

Various serum biomarkers have been found to be associated with neurodevelopmental outcome. In a study of infants undergoing congenital heart surgery aged 6 weeks and younger, postoperative lactic acid level correlated with survival and neurodevelopmental outcome. Adverse survivors, or those survivors with suboptimal neurodevelopmental outcomes, had a higher peak lactate concentration (7.9 vs. 6.5 mmol/liter) and a longer time to plasma lactate normalization (16 vs. 11 hours) when compared with those survivors with normal or intact neurodevelopmental outcomes.⁶⁴

Brain type natriuretic peptide (BNP) is a serum marker of heart failure that is elevated when right and/or left heart pressures are increased. A study of single ventricle patients in the enalapril trial examined the association of BNP and height with neurodevelopmental outcomes.⁶⁵ The investigators discovered that patients with high BNP values and poor growth had worse MDI (Bayley Scales of Infant Development II) scores at 14 months.

CURRENT DATA

Optimizing long-term functional outcome for every patient is a major focus of congenital heart surgery as survival has improved. As mentioned earlier, many institutions now use one or more modalities of intraoperative neuromonitoring. However, there is a paucity of randomized, prospective trials and there remains considerable debate about the benefit, if any, that intraoperative neuromonitoring provides. Many single-institution case-control, observational, and retrospective studies have been conducted.

Surgeons at one institution discussed their approach to multimodality monitoring and reviewed available evidence.⁶⁶ Clark and colleagues use NIRS, TCD, EEG, and SEP and intervene when NIRS decreases more than 20% from baseline. However, they admit that this threshold is derived from adult studies and that a pediatric threshold has not been defined. Their use of TCD is no different than what has been reported previously; that is, they use TCD for detecting alterations in

cerebral blood flow and emboli. The surgeons also describe their preference for four-channel EEG in patients younger than 2 years (eight-channel EEG for patients older than 2 years) and their routine use of SEP in patients older than 2 years. Clark and colleagues then provide a review of the available data for NIRS, TCD, EEG, SEP, and multimodality monitoring and conclude there are no data that support the routine use of these modalities in the operating room.

Another report describes an institution's attempts to decrease the risk of neurologic injury to neonates undergoing cardiac surgery through the use of intraoperative neuromonitoring.⁶⁷ Khan and Fraser review their protocol for neonatal cardiopulmonary bypass and discuss their use of bilateral NIRS and TCD to guide antegrade cerebral perfusion to minimize time of deep hypothermic circulatory arrest. They review the literature on intraoperative NIRS and TCD and describe their plans for future neuroprotection studies. The authors conclude that their cardiopulmonary bypass strategy is based on the data currently available but that further studies of long-term neurologic outcomes are warranted.

A systematic review done by a group that included pediatric cardiac surgeons, a pediatric neurologist, and a pediatric anesthesiologist concluded that data supporting the use of current neuromonitoring and neuroprotective techniques are limited.⁶⁸ The literature review encompasses 20 years (1990 to 2010) and initially identified 527 manuscripts. Review of this group of abstracts resulted in 187 potential manuscripts based on inclusion and exclusion criteria. Another review generated the final list of 162 manuscripts. The primary outcome was evidence of structural brain injury or functional disability and was demonstrated in only 43% of the manuscripts analyzed. Only 13% of the studies were randomized prospective trials. Manuscript categories analyzed included blood gas management, hematocrit, EEG, cooling, glycemic control, S-100 β , TCD, NIRS, and deep hypothermic circulatory arrest/low-flow cardiopulmonary bypass/RCP. The largest groups were those of deep hypothermic circulatory arrest/low-flow cardiopulmonary bypass/RCP ($n = 44$ manuscripts) followed by NIRS ($n = 35$). Only two studies (1.3%) were graded as procedures or treatments that are recommended because the benefits clearly outweigh the risks (American College of Cardiology/American Heart Association level of evidence grade class I, level B).⁶⁸ These two studies examined the effect of hemodilution on neurodevelopmental outcomes; results suggest that severe hemodilution (probably 24% or less) is associated with adverse neurodevelopmental outcomes.⁶⁸ No category reached class I, level A—demonstration of a clear benefit and recommended as effective.⁶⁸ Since this systematic review was done, few manuscripts have been added to the literature on the subject of intraoperative neuromonitoring.

Neuroprotection

The aforementioned study that reviewed 20 years of literature on neuroprotection included examination of many aspects of neuroprotection done during the

perioperative period, including some of the following: blood gas management, hematocrit, EEG, cooling, glyce-mic control, S-100 β , TCD, NIRS, and deep hypo-thermic circulatory arrest/low-flow cardiopulmonary bypass/RCP. As mentioned, of the 162 manuscripts that met inclusion criteria, only two were recommended as having benefits that outweighed the risks. Both involved hemodilution and advised that the hematocrit stay at or above 24% during cardiopulmonary bypass cases. The study also reviewed the use of perioperative medications, including phenobarbital, erythropoietin, allopurinol, aprotinin, tranexamic acid, steroids, methylprednisolone, and dexamethasone. There are no studies that report a benefit to using any of these medi-cations. Most centers have adopted protocols for neu-roprotection and neuromonitoring that they feel are safe and work best at their institution. At the Children's Hospital of Philadelphia, the neuromonitoring and neu-roprotection strategy currently includes the following: The cardiopulmonary bypass pump setup contains a bubble detector and continuous arterial blood gas and venous saturation monitors. The priming protocol con-tains Solu-Medrol. The goal hematocrit for patients younger than 1 year of age is higher than 30%. For patients older than 1 year, the goal hematocrit is higher than 25%. While on cardiopulmonary bypass, the goal mean arterial pressure is 25 to 55 mm Hg for neonates weighing 5 kg or less. This increases to 60 to 80 mm Hg for patients aged 11 years and older and weighing more than 40 kg. Alpha stat is used at normothermia and when warming. pH stat is used when cooling and when maintaining hypothermia. The arterial-to-patient temperature gradient is maintained between 8° C and 10° C when cooling. Cooling is performed for at least 15 minutes prior to circulatory arrest, and the arterial temperature is maintained higher than 15° C. Warming is also done with the arterial-to-patient temperature gradient maintained at 8° C to 10° C.

Many questions about neurodevelopmental outcomes, neuromonitoring, and neuroprotection remain unan-swered. It is clear now that many patients have preopera-tive cerebral abnormalities. Some patients with a structurally and functionally normal brain are at higher risk of brain injury during congenital heart surgery because of a genetic predisposition. Longer-term follow-up will continue to help plan future strategies to optimize neurodevelopmental outcomes. Available modalities of intraoperative neuromonitoring include EEG, TCD, NIRS, and SSEP. Whether these techniques prevent brain injury remains to be seen. A prospective, randomized study with longer-term neurodevelopmental outcomes has not been accomplished. This study may never be accomplished because many centers have already adopted these technologies as standard without proof of benefit. The hardware used in the cardiopulmonary bypass circuit continues to evolve. However, there is still no consensus on what type of cerebral perfusion, if any, is best during deep hypothermic circulatory arrest. The best outcomes in such a heterogeneous field of congenital heart surgery are often achieved by doing what is com-fortable and safe for an individual surgeon, team, and institution.

SUMMARY

HISTORY OF PEDIATRIC TRACHEAL SURGERY

In 2000, the Congenital Heart Surgery Nomenclature and Database Project classified congenital tracheal stenosis as congenital–complete tracheal rings, postintubation, traumatic, or congenital web.¹ Localized stenosis was defined as less than 50% of the tracheal length, and long-segment stenosis as greater than 50% of the tracheal length.¹ The initial classification of tracheal stenosis had been proposed by Drs. Cantrell and Guild from the University of Washington, Seattle, in 1964.² They classified these patients into three morphologic types: (1) generalized hypoplasia, (2) funnel-like stenosis, and (3) segmental stenosis. They also noted the frequent association of a tracheal right upper lobe bronchus that is present in 20% of these patients (Fig. 112-1). Dr. Hermes Grillo from Massachusetts General Hospital is considered to be the father of tracheal surgery. In a series of landmark publications in the 1960s, he defined the blood supply of the trachea, the surgical approach to the trachea, and tracheal release procedures for resection.^{3,4} The first successful operation for congenital stenosis of the trachea was reported by Dr. Ken Kimura from Kobe Children's Hospital in Kobe, Japan, in 1982.⁵ He used a costal cartilage graft to augment the tracheal lumen of a 12-month-old infant with tracheal stenosis secondary to complete tracheal rings (cartilage tracheoplasty). The use of pericardium to augment the tracheal lumen was first performed by Dr. Farouk Idriss from Children's Memorial Hospital, Chicago, in 1982.⁶ The operation was facilitated by the use of cardiopulmonary bypass for respiratory support during the procedure. Slide tracheoplasty was first reported by Drs. Victor Tsang and Peter

Goldstraw from Brompton Hospital in London, England, in 1989.⁷ Its use in children was popularized by Dr. Grillo and his associates.⁸ Drs. Claus Herberhold and Martin Elliott from Great Ormond Street Hospital, London, performed the first successful tracheal homograft to augment the lumen of a patient with a failed prior intervention for tracheal stenosis from congenital tracheal rings in 1994.⁹ Drs. Carl Backer and Constantine Mavroudis reported the use of a free tracheal autograft for infants with congenital tracheal stenosis in 1998, 2 years after they performed the first operation.¹⁰ Pulmonary artery sling repair was first performed by Dr. Willis J. Potts at Children's Memorial Hospital in 1953.¹¹ The left pulmonary artery was divided at its origin from the right pulmonary artery and reanastomosed anterior to the trachea.

CLINICAL PRESENTATION AND DIAGNOSTIC TECHNIQUES

The two most common congenital tracheal anomalies in infants and children are tracheomalacia and tracheal stenosis. Congenital tracheal stenosis is most commonly caused by complete cartilage tracheal rings, and it is the most common indication for surgical intervention.¹² The normal trachea has an anterior arch-shaped cartilage and a posterior membranous trachea. In children with complete tracheal rings, the cartilage ring is circumferential and the membranous trachea is absent (Fig. 112-2). In contrast, tracheomalacia is associated with a normal or sometimes broad membranous trachea. Failure of the C-shaped cartilaginous portion to maintain a minimum of rigidity to the trachea results in “floppiness,” which results in functional tracheal narrowing, particularly

FIGURE 112-1 ■ The three morphologic variants of congenital stenosis of the trachea. *Left*, Generalized hypoplasia; *center*, funnel-like stenosis; *right*, segmental stenosis. The occurrence of an anomalous right upper lobe bronchus (or tracheal right upper lobe) (*right*) is most common in the segmental form. (From Cantrell JR, Guild HG: Congenital stenosis of the trachea. *Am J Surg* 108:297, 1964.)

during expiration. The circumference of the trachea is typically normal during inspiration, or when a patient is intubated (e.g., for a computed tomography [CT] study). Tracheomalacia is a chronic condition that infrequently requires surgical intervention. It often improves with time and growth of the child. Patients with tracheal stenosis often have associated anomalies, most commonly pulmonary artery sling and congenital cardiac anomalies.¹³ Pulmonary artery sling is present in a third of patients with congenital tracheal stenosis. Major intracardiac anomalies are present in 25% of the patients with congenital tracheal stenosis.

The diagnosis of congenital tracheal stenosis should be suspected in any infant who has stridor (noisy breathing), respiratory distress, apnea, cyanosis, wheezing, retractions, or respiratory failure requiring intubation. Tracheal stenosis can result in a difficult intubation (e.g., the endotracheal tube selected for the patient's size fails to pass into a normal location in the trachea), and this traumatization of the trachea can cause future tracheal stenosis.

Patients with known or suspected tracheal problems should be evaluated with a chest radiograph, CT or magnetic resonance imaging (MRI) (or both), bronchoscopy, and echocardiography (Box 112-1). The chest radiograph often demonstrates the diminutive nature of the tracheal lumen. It reveals lung agenesis or hypoplasia. A CT scan or MRI shows the tracheal lumen in cross section and provides a measurement of the tracheal stenosis. A tracheal right upper lobe can be identified if present. Three-dimensional reconstruction can generate a very good representation of the tracheal pathology (Fig. 112-3).¹⁴

In our experience, CT has been more helpful than MRI because it is usually quicker (i.e., requires less sedation, or obviates the need for intubation), and there is less movement artifact. It can be performed as a dynamic expiratory CT scan—that is, in synchrony with the child's

BOX 112-1 Diagnostic Techniques for Infants with Complete Tracheal Rings

- Chest radiography
- Computed tomography (CT) with contrast, including three-dimensional reconstruction or dynamic CT
- Rigid bronchoscopy
- Echocardiography (to rule out pulmonary artery sling, congenital cardiac anomalies)

inspiration and expiration. End-inspiratory and dynamic expiratory volumetric imaging can be obtained. This type of dynamic study is helpful when evaluating children who might have tracheomalacia but do not fit a typical symptomatic pattern.¹⁵ However, CT results in a much higher radiation burden, which should be taken into consideration if the child is likely to require repeated imaging studies. Contrast tracheobronchography, which generates high-quality images, is still used sometimes. However, CT generates such excellent images that the risks of contrast tracheograms mostly outweigh the benefits, so this technique is usually used only in conjunction with a catheterization. A pulmonary artery sling can be demonstrated by CT if the CT is performed with contrast, or by MRI. For the sick neonate who is transferred with a critically positioned endotracheal tube and congenital tracheal stenosis, transthoracic echocardiography is the diagnostic procedure of choice to demonstrate a pulmonary artery sling.¹⁶ Echocardiography should be performed on all of these infants because of the 25% incidence of congenital heart disease found in patients with congenital tracheal stenosis.¹³

The most important diagnostic procedure in all patients is a rigid bronchoscopy. This can be performed as a separate procedure before the planned tracheal operation, or it can be done at the time of the tracheal

FIGURE 112-2 ■ The trachea of an infant with long-segment tracheal stenosis secondary to complete tracheal rings. There are three normal tracheal rings immediately below the cricoid. The upper cutaway shows a normal tracheal ring with the anterior cartilage and flat posterior membranous trachea. This is followed by 18 complete tracheal rings that progress almost to the carina, one of which, shown in the lower cutaway, is a complete cartilage ring with a substantially reduced tracheal lumen. The tracheal lumen in some of these infants is as small as 1.5 to 2 mm.

procedure. In some severe cases, distal visualization of the trachea cannot be obtained by bronchoscopy because of the risk of occluding the tracheal lumen. The child can then be placed on cardiopulmonary bypass, and bronchoscopy can be performed safely.¹⁷

SURGICAL TECHNIQUES

General Principles

In general, the incidence of airway complications, including anastomotic dehiscence, rises with the length or amount of trachea that is resected. Younger patients and reoperative tracheal procedures also have significantly higher complication rates.¹⁸ Tracheal anatomy, including blood supply, should be well understood. Grillo expressed concern about devascularization in adults,³ but this appears to be less important in children, who have an excellent mediastinal blood supply. Right and left recurrent laryngeal nerves should be protected at all cost. A

FIGURE 112-3 ■ Computed tomography (CT) (inset) with three-dimensional reconstruction reveals a significant tracheal stenosis in the midportion of this child's trachea. The pathology at the time of surgery was essentially identical to the pathology indicated by the CT scan. A, Anterior; P, posterior; R, right.

good relationship with pediatric otorhinolaryngologists with special expertise in endoscopic and surgical airway management is essential.

Postoperative management differs with the age of the child. For older children, adult principles can be applied, and a "chin stitch" can be used to prevent neck extension. In all cases, a flexible bronchoscopy is performed at 5 to 7 postoperative days. Younger children can be fitted with a neck prosthesis to prevent important neck excursions, but this is rarely used. It may be best to leave neonates and young infants sedated and intubated for 5 to 7 days, and to perform flexible bronchoscopic examination before extubation.

Tracheal Resection

Cantrell and Guild published an early report of a successful tracheal resection in a child in 1964, and they also reported the three morphologic varieties of congenital tracheal stenosis.² The 7-year-old patient had a tracheal right upper lobe and a bridging bronchus to the carina. The bridging bronchus, which was stenotic, was excised, and the carina was brought up to the main trachea. An anastomosis was performed with interrupted sutures of braided stainless steel. The child survived the operation and was asymptomatic on follow-up.

Tracheal stenosis amenable to tracheal resection with end-to-end anastomosis was originally thought to be feasible for stenosis involving up to 50% of the total tracheal length. However, a report from Massachusetts General

Hospital has indicated that resections of more than 30% of the trachea have a substantial failure rate.¹⁹ We believe that tracheal resection is the preferred technique if the stenosis is less than a third of the total tracheal length. This is usually six to eight complete tracheal rings.

We use the technique developed by Grillo for tracheal resection and reanastomosis (TRR).²⁰ In adults, most TRRs are performed via a transverse cervical (“collar”) incision. The airway can be safely managed intraoperatively with careful endotracheal tube positioning. In children, especially small children and infants, control of the airway is much more precarious. As in most experienced pediatric centers, we believe that most if not all tracheal resections in younger children should be performed through a median sternotomy approach with cardiopulmonary bypass. If the tracheal stenosis extends up to the cricoid, a collar incision is made in the neck, forming a “T” with the median sternotomy incision. This incision tends to heal better than a midline extension of the median sternotomy onto the neck. The strap muscles are divided in the midline. The thymus is partially or entirely excised. The innominate artery and vein are dissected free and encircled with vessel loops. These may then be retracted superiorly or inferiorly to address the various components of the trachea. The aorta is mobilized from its pericardial attachments and retracted with a small pledgeted suture to the left. Care is taken to avoid injury to the right or left recurrent laryngeal nerves. The anterior surface of the trachea is freed from pericardial attachments so that it may be completely visualized from cricoid to carina if necessary.

The site of the stenosis is identified externally. At the site of the stenosis and up to one ring above and below the stenotic segment (at most, two rings above or below), dissection must be performed circumferentially and posteriorly to facilitate the removal of the stenotic portion of the trachea. Attention must be paid to the lateral blood supply of the tracheal wall and a decision made regarding which vessels can be preserved for an adequate blood supply to the eventual anastomosis. In most cases, the carinal attachments are freed, as are the pericardial attachments of the right and left mainstem bronchi. Cardiopulmonary bypass is initiated with a single right atrial and aortic cannula, and the aorta is retracted to the left. Cooling is not necessary, and we aim for a temperature of 32° to 34°C. The trachea is opened in the midline through the extent of the tracheal stenosis. If the stenotic portion can be identified from the outside, bronchoscopic guidance is not needed. Three-dimensional CT scan reconstruction has been used to identify the area of stenosis with enough accuracy to allow opening at the correct site. If the focal area of stenosis cannot be identified externally, intraoperative bronchoscopy, using the illuminated tip of the bronchoscope for guidance, can demonstrate the area of stenosis.

The technique of passing a 25-gauge needle through the lightest portion of the stenosis also is useful for some patients. The anterior tracheal incision is extended proximally and distally until the extent of the complete tracheal rings or stenosis has been encompassed. If this length is less than 30% of the trachea (six to eight complete tracheal rings), the segment is then simply excised.

FIGURE 112-4 ■ Tracheal resection. The localized segment of tracheal stenosis is excised. The trachea is extensively mobilized, specifically in the right and left mainstem bronchi and carina. This allows the trachea to be brought together without tension for an end-to-end anastomosis using interrupted polydioxanone sutures. (From Backer CL, Mavroudis C, Holinger LD: Repair of congenital tracheal stenosis. *Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu* 5:173–186, 2002.)

The two ends are brought together, and the anastomosis is performed with interrupted polydioxanone (PDS) sutures (Fig. 112-4), with the knots tied outside. If there is little tension, it is acceptable to run the posterior wall. Before the anterior sutures are tied, the trachea is suctioned free of secretions and blood with a fine plastic suction catheter. At completion, flexible bronchoscopy is always performed before leaving the operating room. A tension-free anastomosis is the key, and we liberally use the Grillo-derived lateral stay sutures, placed one ring above and one below the anastomosis, to bring the two edges together and take some of the tension away from the suture line itself.

It is important to determine before the resection of tracheal tissue (including the stenotic portion) whether a TRR or a slide tracheoplasty will be performed. In the slide tracheoplasty, the extent of tracheal resection should be minimized to use the tracheal wall as a flap. If the length of the stenosis is too long for a successful end-to-end anastomosis, the operation can be converted to the tracheal autograft technique. Results of tracheal resection in infants and children are shown in Table 112-1.^{19,21-23} Complications include anastomotic leak, restenosis, and tracheomalacia.

Slide Tracheoplasty

Slide tracheoplasty is our preferred technique for long-segment narrowing, typically seen in complete tracheal rings. It was first reported by Tsang and colleagues from Brompton Hospital, London, England, in 1989.⁷ The slide tracheoplasty can be performed through a cervical collar incision or through a median sternotomy approach. The procedure has been performed with and without cardiopulmonary bypass. Only the midportion of the tracheal stenosis is transected (Fig. 112-5). The two tracheal halves are then opened longitudinally, one anteriorly and the other posteriorly. The corners of the transecting tracheal incision are trimmed. Figure 112-6 shows an anterior tracheotomy inferiorly and a posterior tracheotomy superiorly. The two openings are then “slid” together and approximated with interrupted absorbable sutures (Fig. 112-7) or with a continuous absorbable suture. It is

TABLE 112-1 Results of Tracheal Resection in Infants and Children

FIGURE 112-5 ■ Slide tracheoplasty. The trachea is transected at the midpoint of the long-segment congenital tracheal stenosis. The superior position of the trachea is incised posteriorly, and the inferior aspect of the trachea is incised anteriorly. (From Dayan SH, Dunham ME, Backer CL, et al: Slide tracheoplasty in the management of congenital tracheal stenosis. *Ann Otol Rhinol Laryngol* 106:914–919, 1997.)

FIGURE 112-6 ■ Slide tracheoplasty. The upper trachea has been opened posteriorly, and the lower trachea has been opened anteriorly. The corners of the transected trachea are trimmed so that the leading edge will fit into the V-portion of the other component. (From Dayan SH, Dunham ME, Backer CL, et al: Slide tracheoplasty in the management of congenital tracheal stenosis. *Ann Otol Rhinol Laryngol* 106:914–919, 1997.)

FIGURE 112-7 ■ Slide tracheoplasty. The beginning of the long anastomotic suture line is performed with an interrupted 6-0 polydioxanone suture while the patient is on cardiopulmonary bypass. (From Dayan SH, Dunham ME, Backer CL, et al: Slide tracheoplasty in the management of congenital tracheal stenosis. *Ann Otol Rhinol Laryngol* 106:914–919, 1997.)

important to carry the suture as an everting suture line; otherwise, a ledge of cartilage will protrude into the tracheal lumen. Correctly done, the result is a trachea that is half the original length with four times the internal luminal diameter, as seen in [Figure 112-8](#), where the configuration of the anastomosis is shown in the small inset. If the tracheal stenosis extends into one of the right or left mainstem bronchi, the slide incisions can be performed laterally, so that the inferior incision extends onto the superior surface of the narrow bronchus.

The results of slide tracheoplasty are reported in [Table 112-2](#).^{7,8,11,21,24–26} The overall mortality was 12% in 33 patients. Complications include granulation tissue, a figure-eight configuration of the trachea, and recurrent stenosis.^{8,11,27}

Cartilage Tracheoplasty

The first report of a successful surgical procedure for long-segment congenital tracheal stenosis described a cartilage tracheoplasty performed by Kimura and associates⁵ in 1982, at Kobe Children's Hospital in Japan. They operated on a 12-month-old female infant who had had recurrent respiratory distress since birth. The entire trachea was stenotic, as seen by bronchoscopy. The left bronchus was of normal caliber, and the right lung was completely aplastic. Through a median sternotomy incision, the left bronchus was incised and cannulated for ventilation. A longitudinal incision was made through the entire length of the anterior wall of the trachea. Two separate pieces of costal cartilage were used to fill the defect in the anterior wall of the trachea. The grafts were

FIGURE 112-9 ■ Cartilage tracheoplasty. Before the median sternotomy, a segment of cartilage is harvested from the sixth or seventh rib. The cartilage is then tailored to correspond to the subsequent tracheal opening. (From Jaquiss RD, Lusk RP, Spray TL, et al: Repair of long-segment tracheal stenosis in infancy. *J Thorac Cardiovasc Surg* 110:1504–1512, 1995.)

attached to the tracheal edges with interrupted 5-0 Dexon sutures. This patient required prolonged intubation and ventilation but was successfully extubated 2 months postoperatively.

For airway control in the infant, cartilage tracheoplasty for long-segment congenital tracheal stenosis is best performed via a median sternotomy with cardiopulmonary bypass. The midline incision is extended onto the neck, or (preferably) a collar incision is used for further exposure of the trachea in the neck. The cartilage graft can be harvested via the median sternotomy incision (Fig. 112-9). Median sternotomy is performed while preliminary preparation of the cartilage graft takes place. The trachea is dissected and exposed on its anterior surface.

FIGURE 112-10 ■ Cartilage tracheoplasty. Exposure of the trachea through a sternotomy is demonstrated, including the relative positions of bypass cannulas and retraction of the great vessels for optimal exposure. Tracheal incision has been performed to the carina. (From Jaquiss RD, Lusk RP, Spray TL, et al: Repair of long-segment tracheal stenosis in infancy. *J Thorac Cardiovasc Surg* 110:1504–1512, 1995.)

The patient is heparinized and cannulated for cardiopulmonary bypass via the right atrium and ascending aorta. Extracorporeal circulation is initiated, with cooling to 32°C, so the heart remains beating in normal sinus rhythm. Ventilation is stopped. The anterior wall of the stenotic trachea is opened through the extent of the stenosis (Fig. 112-10). Bronchoscopic guidance is often helpful to assess the degree of stenosis. The segment of costal cartilage is then tailored to a size and shape suitable for the anterior opening of the trachea. Care is taken to preserve the perichondrium, which is placed on the luminal surface, and the graft is secured with interrupted absorbable monofilament suture (Fig. 112-11). Intraluminal suture exposure is avoided, and the graft is seated on the tracheotomy rather than being allowed to prolapse into the lumen.

After completion of the graft suture line, the anesthesiologist inflates the lungs with air, and the suture line is confirmed to be airtight, with additional sutures placed as necessary. Bronchoscopy is performed to confirm the tracheal lumen adequacy and to clear retained secretions. The endotracheal tube is repositioned in the midportion of the cartilage graft. The patient is ventilated and weaned from cardiopulmonary bypass. The tracheal suture line can be sealed with biological glue. Hemoclips are placed in the soft tissue adjacent to the trachea to mark the location of the cartilage graft. Sternotomy is closed in the standard fashion. Patients are maintained on heavy sedation and with muscle relaxant to minimize motion of the endotracheal tube in the airway.

FIGURE 112-11 ■ Cartilage tracheoplasty. Placement of the cartilage graft is indicated. The graft is oriented with preserved perichondrium placed on the luminal side and secured with interrupted sutures. Intraluminal suture exposure is avoided, and the graft is seated on the tracheal opening, rather than being allowed to prolapse into the lumen. (From Jaquiss RD, Lusk RP, Spray TL, et al: Repair of long-segment tracheal stenosis in infancy. *J Thorac Cardiovasc Surg* 110:1504–1512, 1995.)

One week after the procedure, the patient is reexamined with bronchoscopy. If necessary, granulation tissue is removed and secretions are suctioned. If the airway appears to be stable and adequately healed, the patient is weaned from the ventilator over the next several days and extubated. Follow-up bronchoscopies are performed as necessary until the trachea is cleared of granulation tissue.

Long-term follow-up of these infants has shown that the graft becomes incorporated into the tracheal structure and grows with the patient. In addition, reepithelialization of the graft site with ciliated columnar epithelium occurs.²⁸ The most common indication for this surgery is a prior failed pericardial or slide tracheoplasty.²⁹

Pericardial Tracheoplasty

Pericardial tracheoplasty was first performed by Idriss in 1984 at Children's Memorial Hospital.⁶ This procedure also marked the first use of cardiopulmonary bypass for a patient undergoing an operation for complete tracheal rings. Idriss reported on five infants with long-segment tracheal stenosis, all operated on through a median sternotomy with extracorporeal circulation, and all had a pericardial patch inserted to augment the tracheal lumen. There were no deaths or infections. This technique was the procedure of choice at Children's Memorial Hospital for the next 15 years. However, it was not used often in other centers because of problems related to granulation

tissue formation, the need for repeated bronchoscopies for airway clearance, and the need for repeat operations for restenosis.²⁹ The typical approach was through a median sternotomy, with cardiopulmonary bypass for respiratory support.

The approach is similar to that used for TRR. Once the full extent of the tracheal stenosis has been opened, a suitably shaped pericardial patch is fashioned. The patch should be oversized in both width and length, because some shrinking will occur over time. The patch is made of autologous pericardium and is not treated with glutaraldehyde but simply kept in a saline-soaked sponge during the dissection and opening of the trachea. The patch is anchored in place using interrupted or running Vicryl (Polyglactin 910; Ethicon, Somerville, NJ) or PDS sutures (Fig. 112-12).

The suturing begins in the area of the carina, which is the most critical location. This area is chosen because it is the most inferior point of the dissection, and once the lower portion of the patch is in place, less blood and fluid tend to accumulate in the tracheal lumen. A completion bronchoscopy is performed, and the endotracheal tube is replaced and repositioned under direct vision. The patient is ventilated, and the anesthesiologist inflates the lungs to a pressure of 35 or 40 cm H₂O to test the patch for air leaks, which are controlled with additional sutures. The patient is then ventilated and weaned from cardiopulmonary bypass. The heparin is reversed with

FIGURE 112-12 ■ A completed pericardial patch tracheoplasty. The pericardium is anchored with interrupted Vicryl sutures. In cross section (*inset*), the tracheal lumen is now normal in size. (From Backer CL, Mavroudis C, Gerber ME, et al: Tracheal surgery in children: an 18-year review of four techniques. *Eur J Cardiothorac Surg* 19:777–784, 2001.)

protamine. The edges of the patch are sealed with a very fine spray of biological glue. The extent of the pericardial patch is marked with small hemoclips placed in the soft tissues of the adjacent mediastinum at the superior and inferior portions of the patch. For prevention of patch tracheomalacia, fine monofilament Prolene sutures are used to take partial-thickness bites of the pericardium and fix it to the posterior wall of the ascending aorta and the innominate artery. This acts as a suspending device, holding the patch open. The patient is kept on muscle relaxants and heavily sedated for 1 week. Repeat bronchoscopy is performed.

If the repair is adequate, with a good tracheal lumen and minimal granulation tissue, the patient is then weaned from the ventilator and extubated in 5 to 7 days. Many of these patients, however, have patch tracheomalacia, necessitating a prolonged period of intubation for 1 or 2 more weeks after the first successful bronchoscopy. Repeat bronchoscopies are performed as needed to clear granulation tissue and retained secretions. Over several months, the patch becomes reepithelialized with pseudostratified columnar epithelium.³⁰

As mentioned, the pericardial tracheoplasty has a low operative mortality rate, but it requires a prolonged hospitalization because patients must be kept intubated for a prolonged time. In addition, these patients require frequent bronchoscopic examinations for resection of granulation tissue, which tends to occur chiefly at the carinal area, where there is a critical junction of the pericardial patch, the carina, and the irritation from the distal end

of the endotracheal tube. In addition, a significant percentage of these patients have required a repeat procedure—a tracheotomy to stent the patch, an intraluminal stenting, or other tracheal reoperations.²⁹ Because of all these chronic problems, we consider this procedure to be essentially obsolete. A small pericardial patch can be helpful, however, as an adjunct when tracheal tissue is lacking, for example, to complete a slide tracheoplasty.

Tracheal Autograft Technique

The principle of the tracheal autograft technique is to shorten the trachea and use the excised piece of trachea as an anterior patch (i.e., as an autograft).¹⁰ Patients are operated on through a median sternotomy, with cardiopulmonary bypass. The trachea is incised anteriorly through the area of stenosis, and the midportion of the stenotic trachea is excised. The posterior trachea is brought together with interrupted 6-0 PDS sutures (Fig. 112-13). This leaves an anterior opening that is then augmented with the autograft.²¹ The corners of the autograft are trimmed so that the autograft fits into the anastomosis. The autograft does not shrink like pericardium and therefore does not need to be oversized. The autograft is sutured in place with multiple interrupted 6-0 PDS sutures (Fig. 112-14). If the autograft is not long enough to completely augment the anterior tracheal lumen, the superior portion of the tracheal opening that remains after autograft insertion can be patched with pericardium or cartilage (Fig. 112-15). Placement of the endotracheal tube depends on the anatomy. If the autograft is low enough, we prefer to keep the tube above the anastomosis to avoid irritation of the suture line from tube friction. Alternatively, the tube can be positioned through the area of the autograft if it is in a superior location. After the patients have been ventilated and assessed for air leaks, they are weaned from cardiopulmonary bypass. The autograft is sealed with glue. If the autograft suture line ends up being compressed by the innominate artery, a cervical strap muscle can be mobilized and brought in as an interposition between the innominate artery and the tracheal autograft. The largest published series using this technique is from Children's Memorial Hospital of Chicago.^{10,13,21} We have used this technique occasionally, but we prefer the slide tracheoplasty when feasible.

Homograft Tracheoplasty

The homograft tracheoplasty technique was first performed in adults by Claus Herberhold of Germany. Herberhold and Elliott first applied the technique to a child in 1994.⁹ Jacobs and colleagues reported the largest series of patients undergoing this procedure.³¹ Most of these patients were infants who had a prior failed operation for complete tracheal rings. Cadaveric trachea is harvested, fixed in formalin, washed in thimerosal, and stored in acetone. The operation is performed through a median sternotomy with the patient on cardiopulmonary bypass. The stenosed tracheal segment is opened to widely patent segments proximally and distally. The anterior cartilage is partially excised, and the posterior tracheal muscle or

FIGURE 112-13 ■ Tracheal autograft. An anterior longitudinal incision is made through the complete extent of the tracheal rings (*left*). The midportion of the trachea is excised (*center*) to be used as the tracheal autograft. The two remaining orifices of the trachea are reapproximated posteriorly (*right*). (From Backer CL, Mavroudis C, Dunham ME, et al: Repair of congenital tracheal stenosis with a free tracheal autograft. *J Thorac Cardiovasc Surg* 113:869–874, 1998.)

FIGURE 112-14 ■ Tracheal autograft. The posterior tracheal anastomosis is performed with interrupted 6-0 polydioxanone sutures (*left*). The corners of the autograft are trimmed (*center*). The autograft is sutured in place to cover the remaining opening in the anterior trachea (*right*). (From Backer CL, Mavroudis C, Dunham ME, et al: Repair of congenital tracheal stenosis with a free tracheal autograft. *J Thorac Cardiovasc Surg* 113:869–874, 1998.)

tracheal wall remains. A temporary silicone rubber intraluminal stent is placed, and absorbable sutures secure the homograft (trimmed appropriately) in position. Regular postoperative bronchoscopic treatments are needed to clear granulation tissue. The stent is removed endoscopically after endothelialization occurs over the homograft. In Jacobs and colleagues' initial report there were 24

patients, most of whom were reoperations.³¹ Four deaths occurred, for an overall mortality rate of 17%. In Jacobs and associates' more recent report of their North American experience with the homograft, there was one early death among six patients.³² The procedure is used only as an alternative for the patient who had a failed previous primary procedure.

FIGURE 112-15 ■ Composite tracheal autograft. **A**, The posterior anastomosis is performed. **B**, The autograft is trimmed, cutting only the inferior corners of the autograft. A portion of pericardium is harvested and tailored. **C**, The autograft is sutured in place anteriorly, adjacent to the carina. The pericardial patch is inserted superiorly to complete the repair. (From Backer CL, Mavroudis C, Gerber ME, et al: Tracheal surgery in children: an 18-year review of four techniques. *Eur J Cardiothorac Surg* 19:777–784, 2001.)

FIGURE 112-16 ■ Pulmonary artery sling. The left pulmonary artery (LPA) originates from the right pulmonary artery (RPA) and acts as a sling, pulling on and compressing the distal trachea and right main bronchus. The *inset* shows anterior compression of the esophagus by the anomalous LPA on the lateral view. *MPA*, Main pulmonary artery. (From Mavroudis C, Backer CL: Vascular rings and pulmonary artery sling. In Mavroudis C, Backer CL, editors: *Pediatric cardiac surgery*, ed 3, Philadelphia, 2003, Mosby, pp 234–250.)

PEDIATRIC TRACHEAL ANOMALIES

Pulmonary Artery Sling

A pulmonary artery sling is found in one third of patients who have tracheal stenosis.¹³ The left pulmonary artery originates anomalously from the right pulmonary artery and courses cranial to the right mainstem bronchus and

posteriorly to the trachea on the way to the left lung. This compresses the right main bronchus and distal trachea (Fig. 112-16). The first pulmonary artery sling repair was reported by Potts from Children's Memorial Hospital.³³ Potts operated on a 5-month-old child who had severe right bronchial compression without a known diagnosis. Potts approached the sling through a right thoracotomy. He made the intraoperative diagnosis of a pulmonary

artery sling with origin of the left pulmonary artery from the right pulmonary artery. After considering several surgical alternatives, including a pneumonectomy, Potts clamped and divided the left pulmonary artery and transposed it anterior to the tracheobronchial tree. He then reanastomosed the site of origin into the right pulmonary artery. The patient survived the operation but was found, almost 25 years later, to have an occluded left pulmonary artery.³⁴

Historically the next series of patients who underwent pulmonary artery sling repair were operated on through a left thoracotomy.³⁵ This allowed better exposure for the anastomosis. However, many of these patients continued to have significant problems with tracheal stenosis and left pulmonary artery stenosis or occlusion. This is because none of the techniques described up to that time had dealt directly with the associated tracheal stenosis that is present in roughly two thirds of patients with pulmonary artery sling. Thus, once the diagnosis of pulmonary artery sling is made, a workup of the airway must be performed in all cases. The current approach is via a median sternotomy with cardiopulmonary bypass, which allows the surgeon to approach both pathologies if necessary.³⁶ Mild hypothermia is used, and the heart remains beating throughout the procedure. The right, left, and main pulmonary arteries are widely mobilized to minimize the tension of the anastomosis. As it passes behind the posterior trachea, the left pulmonary artery may be closely adherent to it and must be dissected off with caution. The left pulmonary artery is divided and transposed anterior to the trachea. It is then reanastomosed to the distal main pulmonary artery, at a site selected to approximate the normal origin of the left pulmonary artery (Fig. 112-17). The anastomosis is performed with running polypropylene suture that is locked at every three to four bites. The tracheal repair is also performed while the patient is on cardiopulmonary bypass. Depend-

ing on the length of the stenosis, TRR or slide tracheoplasty is performed.

Tracheomalacia

Tracheomalacia can be a difficult entity to deal with in the infant and young child. It can be classified as primary or secondary. Causes of secondary tracheomalacia include tracheoesophageal fistula and external compression from vascular structures (i.e., the innominate artery, vascular rings), cardiac structures, congenital cysts, and neoplasms. Tracheomalacia accounts for almost half of all congenital tracheal anomalies that are seen with stridor.³⁷ Symptoms depend on the location, length, and severity of the pathology. Intrathoracic tracheomalacia typically produces expiratory stridor or wheezing, which mimics asthma. Symptoms also may include a harsh barking cough, hyperextension of the neck, recurrent respiratory infections, and, when associated with compression by an anomalous innominate artery, reflex apnea.

Lateral chest radiograph shows narrowing of the trachea during expiration. The diagnosis is confirmed at bronchoscopy if spontaneous respiration is maintained during bronchoscopy—the wide posterior membranous trachea is observed to collapse anteriorly during expiration. These dynamics are not observed when the child is paralyzed and ventilated with positive pressure. Dynamic CT with contrast medium is performed after bronchoscopy to define the nature of underlying suspected extrinsic compression.

Most patients with mild to moderate tracheomalacia eventually grow to the point where the tracheomalacia does not require surgical intervention. However, a small number of patients who have severe tracheomalacia require intubation, ventilation, and usually very high positive end-expiratory pressure (PEEP) to keep the airway open and allow adequate ventilation of the patient.

FIGURE 112-17 ■ Pulmonary artery sling repair. The right pulmonary artery (RPA) origin of the left pulmonary artery (LPA) has been oversewn with interrupted sutures (to prevent RPA stenosis). The LPA has been anastomosed to an opening created in the main pulmonary artery (MPA), again with interrupted sutures. The LPA is now anterior to the trachea.

For these severe cases of tracheomalacia, there are several surgical alternatives.

Secondary tracheomalacia is always treated by treating the offending compressing structure first—for example, by repair of a vascular ring or by fixation of an innominate artery. The trachea itself is typically left alone with the anticipation that decompression in conjunction with the growth of the child will result in a more stable airway.

For primary tracheomalacia, one option is tracheostomy. This may obviate the need for positive pressure ventilation because the tracheostomy tube holds open the trachea. With associated bronchomalacia, PEEP may be necessary. Increasingly, these patients are discharged home on ventilation. Many children's hospitals have a separate service for those who become chronically ventilator dependent for a variety of reasons. As the trachea matures and the cartilage gains more strength, these patients can eventually be weaned from their ventilators.

A second alternative is to bronchoscopically place a balloon-expandable wire stent (Fig. 112-18). Stents are usually a procedure of last resort in pediatric airway surgery. However, for severe primary tracheomalacia in patients who are usually ventilator dependent, this can be a life-saving procedure. The largest experience in infants is with the Palmaz stent (Johnson & Johnson International Systems, Warren, NJ).^{38,39} The most common indications in the series from Children's Memorial in Chicago occurred after pericardial tracheoplasty or in patients with tetralogy of Fallot and absent pulmonary valve who had severe compression of the tracheobronchial tree

from enlarged pulmonary arteries. These stents were effective in selected patients, but several patients had complications from significant granulation tissue formation. Again, stents are usually used as a measure of last resort in infants who have not responded to tracheostomy and positive pressure ventilation.

A surgical procedure for infants with tracheomalacia was reported by Hagl and associates from Heidelberg, Germany.⁴⁰ This operation was performed either through a thoracotomy or via a median sternotomy approach. External stabilization of the severely dysplastic distal trachea (six patients) or left main bronchus (two patients) was achieved by suspending the malacic segment in an oversized and longitudinally opened, ring-reinforced polytetrafluoroethylene prosthesis. Multiple pledgeted sutures were placed extramucosally to the dysplastic tracheal wall and the dyskinetic pars membranacea, as well as to the polytetrafluoroethylene prosthesis in a radial orientation. Guided by simultaneous video-assisted bronchoscopy, reexpansion of the collapsed segments was achieved by gentle traction on the sutures while tying (Fig. 112-19). Hagl and associates reported excellent results in six of seven patients. Long-term results are unknown.

Postintubation Stenosis

The largest series of pediatric patients undergoing tracheal surgery for a postintubation stenosis was reported from Massachusetts General Hospital.¹⁹ Wright and colleagues reported 72 patients evaluated for postintubation

FIGURE 112-18 ■ Palmaz stent insertion in a child with severe tracheomalacia. **A**, The Palmaz stent (mounted on a balloon-tipped catheter) has been positioned in the mid trachea. Positioning of the stent is with both fluoroscopy and bronchoscopy. **B**, The balloon is inflated, compressing the stent against the tracheal wall. **C**, The balloon catheter has been removed, and the stent is now in place. The tracheal lumen is held open by the stent.

FIGURE 112-19 ■ Cross-sectional view of tracheal external stabilization with “onlay” fixation of the flaccid pars membranacea and free suspension of the malacic cartilaginous portions within an oversized polytetrafluoroethylene prosthesis. (From Hagl S, Jakob H, Sebening C, et al: External stabilization of long-segment tracheobronchomalacia guided by intraoperative bronchoscopy. *Ann Thorac Surg* 64:1412–1421, 1997.)

stenosis during an almost 25-year period. Of these patients, 31 were treated with tracheal resection and 17 were treated with laryngotracheal resection. Postintubation tracheal stenosis typically occurs from a stricture caused by scarring at the site of compression of the tracheal mucosa by the balloon from the endotracheal tube. Historically, balloons were used with low volume and high pressure. Since converting to high-volume, low-pressure balloons, the incidence of postintubation stenosis has diminished significantly. Evaluation of postintubation stenosis is chiefly with bronchoscopy. The larynx should undergo a detailed examination to identify commonly associated supraglottic (arytenoid scarring and fixation), glottic (vocal cord paralysis or granulomas), or proximal subglottic pathology. Here again, the connection with a pediatric otolaryngologist is paramount. These commonly associated problems may require attention before the tracheal stenosis is repaired. The technical details of the tracheal resection for these patients are similar to those of resection for patients with congenital stenosis secondary to complete tracheal rings.

Tracheal Web

Web-like diaphragms most often occur at the subcricoid level. These webs typically do not involve a significant length of the trachea. Tracheal webs are evaluated in a fashion similar to that used for other patients with tracheal stenosis, and bronchoscopy continues to be the primary diagnostic tool. Tracheal webs have been removed or excised bronchoscopically with biopsy forceps and occasionally with the use of an insulating cauterizing

electrode. Laser therapy or balloon dilation also may be successful. If this should fail, a tracheostomy done below the web may be a temporary solution, allowing the patient to grow and have a definitive resection later in life. In most cases, these webs are cared for by the pediatric otolaryngologist, with only occasional need for tracheal resection by the thoracic surgeon.

SUMMARY

The most common indication for a surgical procedure on the trachea of an infant or small child is tracheal stenosis secondary to complete tracheal rings. Close cooperation between the pediatric cardiothoracic surgeons and the otolaryngologists is essential. We approach all cases via a median sternotomy and perform the repair on beating-heart cardiopulmonary bypass. We prefer TRR for short segments (six to eight tracheal rings, one third of the trachea), and slide tracheoplasty for long-segment stenosis. If the patient has an associated pulmonary artery sling or intracardiac anomaly, that lesion should be repaired simultaneously. Bronchoscopic expertise is essential to make the diagnosis, for intraoperative management, and for postoperative airway management and clearance. The outlook for these patients has evolved significantly from the mid 1970s, when most of these patients died, to the current era—the mortality rate for complete tracheal rings is now less than 15%. The postoperative management of these patients is complex, often because of comorbid conditions, and requires extreme attention to detail and vigilance.

Included under the rubric of congenital heart defects are abnormalities involving the distal transverse arch and proximal descending aorta. Clinical manifestations range widely, from severe congestive heart failure or debilitating stridor to mere incidental finding on routine evaluation. The treatment of these conditions represents the first procedures performed for congenital cardiovascular malformations. The first surgical closure of a patent ductus arteriosus (PDA), performed by Dr. Robert Gross in 1938, opened the era of pediatric cardiac surgery.

PATENT DUCTUS ARTERIOSUS

Introduction

The prevalence of PDA at several days of age varies from 20% to 80% and varies inversely with gestational age and birth weight.¹ Between 1998 and 2008, the Nationwide Inpatient Sample database demonstrated increase in the prevalence of PDA in the United States from 1.9 to 2.8 per 1000 live births, likely because of increased detection and improvements in prenatal and neonatal care.² It is

frequently associated with other heart defects ranging in severity from patent foramen ovale to complex congenital malformations. Several genetic defects have been implicated in the development of PDA, including genes that encode prostaglandin receptors and regulators of smooth muscle cell contraction.³⁻⁵

Pathophysiology and Natural History

Although the ductus arteriosus shunts mostly right to left in utero, expansion of the lungs shortly after birth results in a decline in the pulmonary vascular resistance and increased pulmonary blood flow and arterial oxygen tension. Ductal closure usually occurs within the first several hours after birth, and is thought to be mediated by loss of the placental source of prostaglandins, increased degradation of prostaglandins within the lungs, and increased arterial oxygen tension, which stimulate constriction of smooth muscle cells within the wall of the ductus. The prostaglandin-mediated mechanism is most active in the ductus of premature infants, whereas oxygen tension primarily promotes ductal closure in the term infant, likely because of differences in cyclooxygenase (COX) isoforms present in the ductal tissue at various stages of gestation.⁶ Thus, the PDA of a term infant is generally unresponsive to COX inhibition, whereas the PDA of a premature infant frequently responds.

Spontaneous closure of the ductus within 4 days occurs in 90% to 95% of full-term infants and in 80% to 90% of premature infants at 30 to 37 weeks' gestation.⁷ The rate of spontaneous closure is inversely proportional to birthweight, with only 50% spontaneous closure in extremely low-birthweight infants (500-999 g).⁸ In premature infants, PDA increases the risk of prolonged ventilation and oxygen requirements, pulmonary hemorrhage, and bronchopulmonary dysplasia.⁹⁻¹¹ The diastolic steal is associated with renal hypoperfusion, intestinal ischemia, necrotizing enterocolitis (NEC), reduced middle cerebral artery blood flow velocity, and increased risk of intraventricular hemorrhage.¹²⁻¹⁸ The long-term persistence of PDA is associated with development of endocarditis, congestive heart failure, and eventual development of irreversible pulmonary vascular obstructive disease. Estimated mortality without intervention is 60% by 60 years of age.¹⁹

Clinical Presentation

Presentation ranges from asymptomatic murmur on examination to symptoms of congestive heart failure caused by large left-to-right shunting. Manifestations of pulmonary overcirculation include hypotension, pulmonary edema, and failure to thrive in infants and children. Neonates, particularly premature neonates, may demonstrate intestinal malperfusion and renal insufficiency in addition to respiratory compromise. Cyanosis is occasionally the presenting symptom in older patients with pulmonary hypertension.

Diagnosis

Physical examination reveals the presence of a "to and fro" murmur heard best from the left upper sternal

FIGURE 113-1 ■ Echocardiographic appearance of the patent ductus arteriosus (PDA). Note the insertion just distal to the takeoff of the left subclavian artery.

border, and leads to suspicion of PDA. Chest radiography may show cardiomegaly, signs of pulmonary congestion, and pulmonary edema. Transthoracic echocardiography is used to make the diagnosis (Fig. 113-1). Retrograde flow in the descending aorta indicates significant left-to-right shunting. The presence of a left-sided aortic arch must be confirmed if surgical therapy is contemplated, as this influences the choice of incision. Continuous left-to-right shunting through the ductus is expected, and the presence of right-to-left shunting or bidirectional shunting should raise suspicion for pulmonary hypertension. In adults, echocardiographic windows may be suboptimal, and computed tomography (CT) or magnetic resonance angiography may be necessary to establish the diagnosis. Diagnostic cardiac catheterization is only necessary if pulmonary hypertension is suspected.

Treatment

Medical

Medical treatment of PDA can be separated into (1) management of heart failure and (2) pharmacologic closure in premature neonates. Management of heart failure focuses on reducing the clinical impact of left to right shunting. Diuretics are the mainstay of therapy in patients with pulmonary congestion, but afterload reduction with angiotensin-converting enzyme inhibitor may be a useful adjunct. In hospitalized patients, strategies to avoid reduction of pulmonary vascular resistance limit the degree of left-to-right shunting, and include maintenance of spontaneous ventilation and avoidance of supplemental oxygen when possible. In intubated patients, an increase in the peak end expiratory pressure can reduce left-to-right shunting.²⁰

Pharmacologic closure of PDA with a COX inhibitor (COXi) in premature neonates, even if asymptomatic, improves the rate of eventual ductal closure and incidence of intraventricular hemorrhage, decreases the need for surgical closure, but does not improve mortality or incidence of NEC. Early treatment of a symptomatic

FIGURE 113-2 ■ Intraoperative view of patent ductus arteriosus before (*left*) and after (*right*) clip placement.

PDA (i.e., when clinical signs first appear) has been shown to decrease the incidence of chronic lung disease, duration of mechanical ventilation, and NEC when compared with late symptomatic treatment (i.e., after signs of congestive cardiac failure).²¹ The COXi indomethacin and ibuprofen are equally effective at producing ductal closure. Closure rate between 60% and 80% is achieved with one course of indomethacin, but the success rate of each subsequent course is 40%.^{22,23} A COXi is ineffective at producing ductal closure in term infants because of the lack of prostaglandin-responsive contractile smooth muscle in the ductal tissue. Complications owing to COXi include renal impairment, intestinal perforation, and NEC.²⁴ A randomized clinical study compared oral paracetamol with ibuprofen in preterm infants and demonstrated that paracetamol may be a medical alternative in the management of PDA.²⁵

Surgical

Premature Infants. In premature infants, surgical therapy is generally reserved for failure of COXi therapy in symptomatic patients or for those who develop contraindications to COXi therapy: NEC, renal dysfunction, and intraventricular hemorrhage. This strategy of reserving surgery for failure of medical therapy can lead to a higher incidence of NEC when compared with early surgery, although no difference in mortality has been demonstrated.²⁶⁻²⁹ Early surgical duct closure allows early institution of full oral feeding, but this does not necessarily translate into shorter hospital stay.³⁰ Yet controversy regarding the indications and timing for surgical therapy remains, and variability in practice patterns have been observed.³¹

Preoperative evaluation focuses on medical stabilization, including detection and appropriate treatment of pre-existing infections prior to surgery. Surgery for premature infants can be performed either in the intensive

care unit or in the operating theater. Surgical ductal ligation is generally performed via left thoracotomy, although video-assisted thoracoscopic surgery (VATS) approach has been described, and the PDA is occluded by placement of an external clip (*Fig. 113-2*). Preoperative imaging must exclude the presence of ductal or pulmonary artery aneurysms, which may necessitate extensive resection and vascular reconstruction rather than simple ductal ligation.³²

Full-Term Infants, Children, and Adults. Pharmacologic closure is ineffective in full-term infants, children, and adults, leaving surgical or transcatheter closure as the only options. Ductal closure is indicated in both symptomatic and asymptomatic patients to reduce the risks of endocarditis and pulmonary hypertension. Asymptomatic infants may undergo elective closure between 1 and 2 years of age to facilitate VATS or transcatheter closure, whereas symptomatic infants should undergo prompt evaluation and closure. The presence of cyanosis and bidirectional shunting through the PDA on echocardiography should prompt preoperative cardiac catheterization to measure pulmonary vascular resistance. If elevated pulmonary vascular resistance is unresponsive to oxygen or nitric oxide, closure is contraindicated.

Options for surgical closure in infants include thoracotomy or VATS (see *Surgical Approaches*). Children and adults are candidates for closure via the transcatheter, thoracotomy, VATS, or sternotomy approaches, depending on the morphology of the PDA. Short length and large diameter of the PDA increase the risk of device embolization during transcatheter closure and bleeding during VATS closure.³³ A severe adverse event rate of approximately 2% is seen with transcatheter closure, with younger age being a significant risk factor.^{34,35} To avoid the risk of recanalization, some advocate ductal division in addition to ligation in children and adults.³⁶ Extensive ductal calcification increases the risk of bleeding during

external ligation by VATS or thoracotomy. In these patients, median sternotomy, cardiopulmonary bypass, and closure through a pulmonary arteriotomy may be the safer alternative.

Prognosis

Operative mortality related to PDA ligation in full-term infants and children is less than 1%.³⁶ Premature infants with multiple comorbidities may have hospital mortality as high as 20%. Complications of surgical ligation include left recurrent laryngeal nerve injury, bleeding, postoperative chylothorax, and development of coarctation. Asymptomatic recurrent laryngeal nerve injury can be detected in up to 7% of patients by systematic endoscopy, and the major risk factor for this injury is birth weight less than 1 kg.³⁷ Symptomatic nerve injury manifested by aspiration of feeds is rare.

COARCTATION OF THE AORTA

Introduction

Narrowing of the thoracic aorta beyond the level of the innominate artery (discrete coarctation of the aorta or transverse arch hypoplasia) represents 4% to 8% of cases of congenital heart disease, with an incidence in the general population estimated at 0.2 per 1000 live births.² Bicuspid aortic valve is an associated finding in up to 50% of patients, and hypoplasia of left heart structures is relatively common. A ventricular septal defect (VSD) may be seen in 30 to 60% of patients, and it may be associated with posterior malalignment of the conal septum leading to left ventricular outflow tract obstruction. Complex congenital heart disease and associated with hypoplasia of the systemic ventricle (hypoplastic left heart syndrome, right dominant atrioventricular canal, transposition of the great arteries with hypoplastic right ventricle) may have associated coarctation that affects management. The incidence of coarctation in patients with right aortic arch is unknown, but it has been estimated to be approximately 4%.³⁸

Anatomy and Pathophysiology

The location and extent of aortic obstruction can vary from patient to patient. Discrete coarctation typically occurs just below the origin of the left subclavian artery at the insertion of the ductus arteriosus (juxtaductal coarctation). More diffuse hypoplasia of the distal arch between the left carotid artery and left subclavian artery occurs more commonly in patients with bovine arterial trunk, in which the innominate artery and the right carotid artery arise within close proximity from the proximal transverse arch. An aberrant right subclavian artery arising distal to the coarctation occurs in approximately 3% of patients.

The etiology of coarctation with hypoplasia of the distal transverse arch is not well defined, but its association with hypoplasia of left heart structures suggests common genetic, hemodynamic, or environmental

mechanisms.³⁹ Discrete coarctation of the aorta at the isthmus likely results from abnormal infiltration of ductal tissue onto the juxtaductal aorta.⁴⁰ Synchronous with ductal closure, the contractile ductal tissue within the aorta constricts, resulting in luminal narrowing of the aorta and development of a posterior shelf. It is not uncommon for the aorta to appear of adequate size in the presence of a patent ductus arteriosus, yet manifest coarctation following ductal closure.

Natural History

If the coarctation is left untreated, the prognosis varies from severe heart failure in infancy to asymptomatic hypertension in older children and adults. Collateral vessels become prominent because of increased flow within the intercostal, internal mammary, and scapular blood vessels. The increased flow within these vessels can be sufficient to reduce the blood pressure gradient between the upper and lower extremities at rest. With exercise, however, the gradient may rise significantly because of the elevated vascular impedance. Upregulation of circulating catecholamines and the renin-angiotensin system leads to systemic hypertension. Left ventricular hypertrophy is a result of elevated systemic vascular resistance. Untreated coarctation is associated with a substantially diminished long-term survival, with 75% mortality by 50 years of age.⁴¹ Death in these patients is usually due to systemic effects of hypertension, including heart failure, intracranial hemorrhage, coronary artery disease, or aortic rupture or dissection.

Clinical Presentation

The clinical presentation varies depending on the age at presentation. Almost half of patients with coarctation will develop symptoms within the first month of life and will often have the preductal subtype of coarctation with hypoplasia of the arch. Neonates with unsuspected critical coarctation usually have systemic hypoperfusion, metabolic acidosis, and congestive heart failure manifested as tachypnea and difficulty feeding. The timing of the onset of symptoms generally correlates with constriction of the PDA, which provides systemic circulatory support for a period of time after birth. As the ductus closes, perfusion to the lower extremities and abdominal viscera becomes compromised, and end-organ failure manifests with renal dysfunction, hepatic failure, intestinal ischemia, and profound metabolic acidosis. On physical examination, prominent upper extremity and weak lower extremity pulses may be found. Neonates presenting in this manner have a high mortality without urgent intervention. With less severe degrees of coarctation, or in the presence of sufficient collateral development, symptoms may not develop until infancy or adolescence. Asymptomatic patients have a murmur or hypertension. Young adults usually demonstrate hypertension refractory to pharmacotherapy, exercise intolerance, headaches, or angina.

The classic physical findings include the presence of brachiofemoral pulse delay, diminished or absent femoral pulses, and a blood pressure gradient between the upper

FIGURE 113-3 ■ Discrete coarctation of the aorta on two-dimensional echocardiography and color Doppler imaging. Although there appears to be mild hypoplasia of the transverse arch, color Doppler does not reveal flow acceleration across this segment.

and lower extremities. In the presence of well-developed collaterals, there might not be a significant gradient between upper and lower extremity blood pressures. A systolic ejection murmur is audible over the base of the heart and left interscapular region. The electrocardiogram may reveal evidence of left ventricular hypertrophy in older patients.

Diagnosis

Infants with severe coarctation may demonstrate radiographic signs of cardiac enlargement and pulmonary congestion. During adolescence or adulthood, the findings can include a “figure-three” configuration resulting from proximal and post-stenotic dilation of the aorta. Notching of the inferior border of the ribs from the development of intercostal collateral vessels is common by adolescence.

The segment of coarctation can usually be visualized easily in neonates and children with two-dimensional echocardiography (Fig. 113-3). Normalized measurements of the transverse aorta, aortic isthmus, and descending aorta must be obtained. In neonates, a z-score less than -2 indicates significant narrowing. In older children and adults, a greater than 50% decrease in diameter at the aortic isthmus should be considered severe coarctation. As mentioned previously, associated VSD, aortic and mitral valvular abnormalities, and ventricular hypoplasia must be ruled out. Pulsed- and continuous-wave Doppler estimates the pressure gradient directly at the area of coarctation. In the neonate, the pressure gradient measured by echocardiography may be confounded by presence of a PDA or severe ventricular dysfunction. Similarly, in the older child or adult, the pressure gradient may underestimate the severity of the narrowing because of the presence of significant collaterals. A peak gradient greater than 20 mm Hg, especially if accompanied by continuous forward flow during diastole in the descending or abdominal aorta, suggests significant aortic coarctation.

It is important to define the anatomy of the aortic arch in patients with coarctation, because hypoplasia of the

transverse arch can alter surgical management. A transverse arch z-score of less than -2 often requires surgical management at the time of coarctation repair. The presence of a “bovine trunk,” in which the innominate artery and left common carotid artery arise as a single trunk, should raise concerns of hypoplasia of the transverse arch between the common trunk and the left subclavian artery.

In older children and adults, the anatomy may be difficult to define with echocardiography because of poor sonographic windows. CT, CT angiography, and magnetic resonance imaging (MRI) have become valuable diagnostic tools in these patients, because they provide superior imaging of the transverse and descending aorta, as well as important information regarding the extent of collateral development. Catheterization with angiography is used to determine the diagnosis and severity of coarctation in patients with disparate clinical and echocardiographic findings. It is also used to determine the degree of coronary artery stenosis in adult patients requiring surgical repair. Transcatheter intervention is preferred for treatment of recoarctation, but its application for native coarctation remains controversial.

Treatment

Patients with significant coarctation or recoarctation are candidates for surgical or transcatheter intervention to reduce the risk of long-term complications. This includes patients with arm-to-leg systolic blood pressure difference greater than or equal to 20 mm Hg, brachiofemoral pulse delay, peak transcoarctation gradient greater than 20 mm Hg at angiography, and those with long-standing hypertension or left ventricular hypertrophy. Elective repair in asymptomatic patients should be performed before 2 years of age, because persistent hypertension following repair has been documented in patients undergoing delayed repair.

Medical Management

Severe neonatal coarctation manifests with profound acidosis from lower extremity hypoperfusion caused by

ductal closure, and it can be associated with moderate to severe ventricular dysfunction. Medical stabilization before operating in these patients improves outcomes compared with emergent operation. Ventilatory and inotropic support and intravenous administration of bicarbonate are used to control the metabolic acidosis and ventricular dysfunction. Prostaglandin E₁ (0.01–0.1 µg/kg/min) is given to reestablish ductal patency, and its efficacy is monitored with serial echocardiograms. Cardiovascular collapse can be difficult to resuscitate medically, and may require extracorporeal membrane oxygenation support (ECMO). A major pitfall of preoperative ECMO support in a patient with coarctation is the inadequacy of lower-body perfusion. Neonatal ECMO cannulation is often performed through the carotid artery and jugular vein. With this approach, however, perfusion distal to the coarctation segment remains compromised, and measures to improve distal perfusion must be pursued immediately. These measures include prostaglandin E₁ infusion, transcatheter intervention (balloon angioplasty), or traditional surgical resection and reanastomosis.

Surgical Repair

Surgical repair may entail anatomic repair versus extra-anatomic bypass. Anatomic repair involves reconstruction with native aortic tissue, patch augmentation, or interposition grafting, and it is the preferred strategy for primary repair and reoperative repair in children. Extra-anatomic ascending aorta to descending aortic bypass is reserved for adults with complex coarctation undergoing concomitant cardiac surgical procedures (valve replacement or coronary artery bypass grafting).

Anatomic repair in children entails resection of the coarctation segment with end-to-end anastomosis of the distal transverse arch to the descending aorta. Primary treatment for neonates and infants is extended end-to-end anastomosis in which (following coarctation resection) the descending aorta is mobilized, advanced, and anastomosed onto the undersurface of the transverse arch at the level of the left carotid artery (Fig. 113-4). Patch angioplasty or interposition grafts are typically necessary for adults and adolescents, in whom limited aortic mobility prevents a tension-free aortic anastomosis. Subclavian flap angioplasty involves division of the left subclavian artery and use of the proximal portion for aortic reconstruction. The flap is placed on the aorta distal to the subclavian artery for traditional coarctation repair, whereas a reverse flap is used to augment the transverse arch when hypoplasia between the left carotid and subclavian artery is encountered. Coarctation in patients with right aortic arch is approached with a right thoracotomy and treated by patch angioplasty rather than extended end-to-end anastomosis.³⁸

Recurrent aortic arch obstruction following previous coarctation repair can be treated surgically with native arch reconstruction, patch aortoplasty, or placement of an interposition graft.⁴² In rare circumstances, ascending-to-descending aortic grafts are used for repair of native or recurrent coarctation associated with significant cardiac disease that requires concomitant surgical

management (coronary artery bypass grafting, aortic valve replacement).⁴³ Access to the descending aorta can be obtained by incising the posterior pericardium and dissecting the supradiaphragmatic aorta. Ascending to abdominal aorta bypass avoids the risk of paraplegia associated with left thoracotomy repair of recoarctation in adults.^{43,44}

During thoracotomy in an older child or adult, large collateral vessels may be encountered and require meticulous hemostasis. To minimize the risk of spinal cord injury, hyperthermia should be treated aggressively, and mild hypothermia (33–35° C) is preferred. Although repair of coarctation through a left thoracotomy does not require circulatory support, partial bypass may be helpful in adolescents and adults in whom collateral vessels are underdeveloped or have been surgically interrupted. Partial left heart bypass is instituted by providing venous drainage (left atrial appendage or pulmonary vein) and arterial cannulation (femoral artery or descending aorta). Native heart ejections are maintained to provide antegrade blood flow to the upper body during the cross-clamp period.

Coarctation and Ventricular Septal Defect

The presence of a VSD can alter the management of coarctation. Elevated resistance to systemic outflow from coarctation or associated left ventricular outflow tract obstruction can drive increased pulmonary blood flow and result in profound heart failure. Factors that influence therapeutic strategy include the size and likelihood of closure of the VSD and the degree of proximal transverse arch hypoplasia. The location of the VSD is an important determinant of the probability of eventual closure, with the highest closure rates seen with muscular VSDs. Surgical options for patients with unrestrictive VSD and coarctation include single-stage and staged repair of both lesions. Single-stage repair of both coarctation and VSD through a midline sternotomy requires cardiopulmonary bypass but is preferred if transverse arch hypoplasia (z-score < -3.0) is present.⁴⁵ Staged repair of the coarctation through a left thoracotomy with or without placement of a pulmonary artery band to control left-to-right shunting avoids the use of cardiopulmonary bypass. This approach is preferable if spontaneous closure of the VSD is likely or if cardiopulmonary bypass is contraindicated.⁴⁶

Transcatheter Intervention

Balloon angioplasty with stenting is an effective treatment for recurrent coarctation of the aorta and is the treatment of choice.⁴⁷ For native coarctation, percutaneous balloon angioplasty with or without stenting is an evolving modality of treatment.⁴⁸ Compared with surgical repair, balloon angioplasty is associated with a higher incidence of restenosis.^{49,50} Acute outcomes of stenting for native coarctation are favorable, but long-term follow-up is lacking.^{51,52} The use of a covered stent instead of a bare metal stent may be associated with decreased recoarctation rate, but it does not prevent aneurysm formation.⁵³

FIGURE 113-4 ■ Techniques for surgical repair of coarctation include (A) end-to-end anastomosis or (B) extended end-to-end anastomosis. C, Intraoperative appearance of coarctation segment (*left*) and extended end-to-end anastomosis (*right*).

Angioplasty and stenting are alternatives to surgery in high-risk patients in whom temporary relief of discrete coarctation is desired. In adults, balloon dilation and stenting of native coarctation has resulted in aneurysm formation, rupture, and aortic dissection, and recoarctation.⁵⁴⁻⁵⁶

Postoperative Complications

Complications specific to coarctation repair include persistent hypertension, mesenteric arteritis, spinal cord ischemia, aneurysm formation, and recurrent coarctation. Significant hypertension can persist in the postop-

erative period despite a successful operation, and intravenous esmolol is effective at controlling this in the acute postoperative period.^{57,58} Acute abdominal pain, thought to be secondary to mesenteric arteritis, was once a common occurrence following coarctation repair. In recent years, the reported incidence of this complication has been low, likely because of improvements in early diagnosis and intervention. Complications related to the thoracotomy and aortic dissection include pneumothorax, chylothorax, and recurrent laryngeal nerve injury. The major risk factor for persistent late hypertension is older age at time of repair, such that 70% of adult patients require ongoing long-term antihypertensive therapy.⁵⁹⁻⁶¹

Prognosis

Operative mortality for neonates and infants with isolated coarctation or coarctation with VSD ranges from 1% to 5%.⁶²⁻⁶⁴ Survival rates at 10 and 30 years following repair are approximately 90% and 70%, which is slightly less than the age-matched general population.⁶⁵ The incidence of recoarctation ranges from 10% to 30% in infants, with younger age being a significant risk factor for recurrence and shorter duration to reintervention.⁶⁶⁻⁷⁰ The presence of a small transverse arch is also a risk factor for reintervention.⁶⁷

In infants, the surgical techniques of extended end-to-end anastomosis and subclavian flap arterioplasty have been associated with the lowest risk of recoarctation in most series.^{71,72} Subclavian artery ligation affects limb development, but it does not result in limitation of life-style.⁶³ In children, adolescents, and adults, patch repair of coarctation with or without luminal ridge resection has been associated with a higher incidence of late aneurysm formation when compared with end-to-end anastomosis or interposition grafting.^{73,74} Extra-anatomic bypass is associated with a low rate of paraplegia and stroke in adults with complex coarctation.⁷⁵ Although low rates of recoarctation have been demonstrated following balloon angioplasty of native coarctation, these results have not been reproduced consistently.^{76,77}

VASCULAR RINGS

Introduction

The term *vascular ring* refers to a vascular anomaly that leads to encirclement of the trachea and esophagus. Included in this discussion are vascular compression syndromes, in which the trachea and esophagus are compressed by vascular structures that do not form a complete ring. Symptomatic vascular rings constitute approximately 1% of all cardiovascular anomalies; however, the prevalence of asymptomatic vascular rings, which are more common than symptomatic rings, is unknown. Associated intracardiac pathology may be present in 10% to 30% of patients and includes VSDs, tetralogy of Fallot, patent ductus arteriosus, and congenitally corrected transposition of the great arteries.

Classification

The Congenital Heart Surgery Nomenclature and Database Project classifies vascular rings and compression syndromes as double aortic arch, right arch/left ligamentum, pulmonary artery sling, and innominate compression.⁷⁸ Double aortic arch and right aortic arch with left-sided ductus are examples of complete rings. Innominate artery compression and pulmonary artery sling, which do not form complete rings, lead to specific compression syndromes.

Anatomy and Pathophysiology

During normal embryologic development of the thoracic great vessels, regression of specific segments of the

FIGURE 113-5 ■ Double aortic arch creating complete ring around aorta and esophagus. (Compliments of Andrew Powell, MD, and Emily Flynn-Thompson, Children's Hospital Boston.)

embryologic aortic arch results in normal development of a left-sided aorta with the typical branching pattern and a normal pulmonary artery. Both a right and left dorsal aorta are present in the embryo during the first 3 weeks of development. Dissolution of the right dorsal aorta leads to persistence of a dominant left dorsal aorta. Abnormal regression of the dorsal aortic segments leads to abnormalities of the aortic arch.

Double Aortic Arch

Failure of the regression of the right fourth arch and persistence of the left fourth arch results in development of a double aortic arch. In this abnormality, two separate arches from the distal ascending aorta travel on opposite sides of the trachea and esophagus and join the descending aorta (Fig. 113-5). The trachea and esophagus are compressed by the two arches, which are connected proximally and distally, thus forming a complete ring. In many cases, one of the arches, typically the left, is either hypoplastic or atretic. The right-sided arch is dominant in 70% to 75% of patients, the left arch is dominant in approximately 20%, and codominance is seen in the remainder. Because the complete ring is created by proximal and distal continuity of the right and left aortic arches, interruption of the ring requires division of one of the arches.

Right Aortic Arch with Left Ligamentum

Right aortic arch results from regression of the left fourth arch and persistence of the right fourth arch, with an incidence that ranges between 0.05% and 0.2% in adult patients with congenital heart disease. A complete vascular ring is formed if there is a left-sided ductus or ligamentum arteriosum. The boundaries of the complete ring are the right aortic arch posteriorly and rightward, the pulmonary artery anteriorly, and the ligamentum arteriosum or ductus arteriosus to the left (Fig. 113-6). The ligamentum arteriosum usually arises from the base of the left subclavian artery and connects to the pulmonary artery. Thus, if there is an aberrant left

FIGURE 113-6 ■ Right aortic arch with left ligamentum arteriosum. **A**, Mirror-image branching. **B**, Aberrant right subclavian artery. (Compliments of Andrew Powell, MD, and Emily Flynn-Thompson, Children's Hospital Boston.)

subclavian artery that arises from the descending aorta, a left ligament is almost always present. Similarly, in patients with mirror-image branching (MIB), the left subclavian artery arises from the proximal ascending aorta. Because the ligament courses anterior to the airway, most patients with MIB do not experience airway compression. Occasionally, however, in a patient with MIB, the ligamentum may connect to the descending aorta (left ligamentum) and create a complete vascular ring (see Fig. 113-6). This arrangement, although uncommon, must be suspected in a patient with MIB and airway compression. In patients with right aortic arch and left ligamentum, the ligamentum may attach to a diverticular remnant of the left fourth arch, referred to as the *diverticulum of Kommerell*. Associated aneurysm of the diverticulum has been described and may contribute to symptoms by direct compression of the trachea and esophagus.⁷⁹ Interruption of the ring is most easily performed by dividing the ligamentum arteriosum or ductus arteriosus, whereas management of the diverticulum is controversial.

Circumflex Retroesophageal Aorta

A rare form of complete vascular ring is the circumflex retroesophageal aortic arch. In this anomaly, the distal transverse arch crosses the midline, posterior to the esophagus, to descend on the contralateral side, thus placing the aortic arch and the descending aorta on the opposite sides of the spine. A complete ring is formed if the ligamentum arteriosum or ductus arteriosus is present

on the side contralateral to the aortic arch. Even if a complete vascular ring is not formed (in the presence of an ipsilateral ligamentum), posterior compression of the esophagus can still occur.⁸⁰ Embryologically, this malformation is a consequence of preservation of the proximal ipsilateral fourth arch (right or left aortic arch), and persistence of the contralateral sixth segment (ligamentum or ductus) and distal portion of the contralateral fourth arch (descending aorta). The two forms of this anomaly are left aortic arch (LAA) with right descending aorta (Fig. 113-7) and right aortic arch with left descending aorta. Circumflex left aortic arch is frequently associated with aberrant origin of the right subclavian artery (RSCA) from the descending aorta. Right aortic arch can be associated with either MIB or aberrant left subclavian artery (LSCA) patterns, but a complete ring only occurs in the presence of a left ligamentum. Cervical aortic arch is an associated finding in some patients consisting of superior extension of the aortic arch into the cervical region. This results from persistence of the right or left third branchial arch and regression of the fourth branchial arches.

Left Aortic Arch and Anomalous (Retroesophageal) Right Subclavian Artery

The most common arch anomaly, present in approximately 0.5% of the population, is the LAA with aberrant RSCA and left-sided ligamentum arteriosum (Fig. 113-8). Embryologically, this anomaly results from normal involution of the right fourth arch and dorsal

FIGURE 113-7 ■ Circumflex left aortic arch with right descending aorta and right ligamentum, creating a complete vascular ring. (Compliments of Andrew Powell, MD, and Emily Flynn-Thompson, Children's Hospital Boston.)

FIGURE 113-8 ■ Aberrant right subclavian artery coursing posterior to esophagus.

aorta, but persistent attachment of the right seventh intersegmental segment to the descending aorta. Most individuals with this anomaly are asymptomatic, but symptoms of dysphagia can occur if this vessel compresses the esophagus as it courses posteriorly. The presence of an aneurysm of the artery or Kommerell diverticulum at its aortic origin is more likely to produce

FIGURE 113-9 ■ Left pulmonary artery (LPA) sling originating from the right pulmonary artery (RPA) and coursing posterior to the trachea. MPA, Main pulmonary artery. (Compliments of Andrew Powell, MD, and Emily Flynn-Thompson, Children's Hospital Boston.)

symptoms from esophageal compression, but it can also result in hematemesis from arterial-esophageal fistula.⁸¹ There have been case reports of LAA, aberrant RSCA, and right ligamentum attaching to the right subclavian artery, which creates a complete vascular ring and tracheal compression.⁸²

Pulmonary Artery Sling

This vascular malformation is formed when the left pulmonary artery (LPA) arises from the right pulmonary artery (RPA), and it courses around the right mainstem bronchus toward the left lung between the airway and the esophagus (Fig. 113-9). In the developing embryo, the pulmonary artery is formed by amalgamation of the sixth branchial arch with postbranchial vessels that arise from the primitive lung bud. If the left postbranchial vessel connects to the right instead of left sixth branchial arch, then a pulmonary artery sling develops. This results in compression of the tracheobronchial tree, most commonly at the distal trachea or the right mainstem bronchus. It is associated with complete tracheal rings in approximately 50% of patients, and has been associated with agenesis of the right lung.⁸³

Innominate Artery Compression Syndrome

Anterior compression of the airway can occur because of an unusual (leftward and posterior) takeoff of the innominate artery from the aorta. The presence of a prominent thymus gland and pectus deformity of the chest wall exacerbate the anterior tracheal compression. Innominate artery compression of the trachea in infants can cause severe biphasic stridor, cyanosis, and respiratory arrest, sometimes referred to as *dying spells*.

Clinical Presentation

Most common forms of presentation include respiratory distress, stridor, dysphagia or a combination of these

FIGURE 113-10 ■ Barium esophagograms demonstrating bilateral compression of the esophagus by a double aortic arch (A) and posterior compression of the esophagus by an aberrant right subclavian artery (B, C) and circumflex aorta (D). Arrow in B-D demonstrates area of compression. LAA, Left aortic arch; RAA, right aortic arch.

symptoms, depending on the underlying lesion. Compression of the esophagus by an aberrant right subclavian artery can produce dysphagia, previously called *dysphagia lusoria* (or “dysphagia by freak of nature”). Patients with pulmonary artery sling can be in severe respiratory compromise, occasionally severe enough to require salvage by preoperative ECMO.⁸⁴ Coarctation of the aorta or hypoplasia of aortic segments can accompany arch abnormalities and manifest as a murmur, hypertension, or blood pressure gradient between extremities. On physical examination, the child may have stridulous breathing that must be differentiated from wheezing or asymmetric breath sounds from unilateral airway compression. Many patients are referred after being treated with bronchodilators for presumed asthma. A pulsatile mass in the neck suggests the presence of a cervical aorta.

Diagnosis

A diagnostic workup for vascular ring should be initiated in a child or adolescent with airway or esophageal symptoms if symptoms are not relieved by medical management. History of recurrent pneumonia, bronchoconstriction that is unresponsive to bronchodilators, and dysphagia to solid foods should raise suspicion and further workup. On chest radiography, the findings include tracheal narrowing at the level of the aortic arch and unclear delineation of the aortic knob. Unilateral hyperinflation of one lung field may suggest obstruction at the mainstem bronchial level.

CT and MRI are the primary modalities to establish the diagnosis and plan an operative procedure.^{85,86} MRI with three-dimensional reconstruction is preferred in most centers to avoid exposure to ionizing radiation (Fig. 113-10).⁸⁷ Specific information that must be obtained includes the course and origin of arterial branches, arch dominance in patients with double aortic arch, location of the ligamentum arteriosum, and the degree of airway or esophageal compression. Airway compression might not be apparent in patients who are intubated and mechanically ventilated, and dynamic imaging during

inspiration and expiration increases the sensitivity of detecting airway compromise. Echocardiography is helpful for delineating the arch anatomy in neonates and infants, but it cannot definitely make the diagnosis of a vascular ring unless there is a double aortic arch and both arches are patent.

Barium esophagography is a reliable initial study for workup of the patient with dysphagia. The most common appearance on esophagogram includes the presence of posterior extrinsic compression in the presence of a right aortic arch, anterior esophageal compression in the presence of a pulmonary artery sling, and extrinsic compression on anteroposterior views of the esophagus in the setting of double aortic arch (Fig. 113-11).

Bronchoscopy is helpful in the assessment of patients with vascular rings and suspected airway compression. Although routine bronchoscopy is not necessary in the setting of a complete vascular ring with clinical or imaging evidence of airway obstruction, it may be useful in situations where the diagnosis or significance of vascular anomaly is unclear. Anterior compression of the trachea by the innominate artery visualized at bronchoscopy may establish the diagnosis and severity of innominate artery compression when noninvasive imaging is equivocal, and thus guide clinical management. Under certain circumstances, bronchoscopy can reveal several separate causes of airway compromise in a patient with a vascular ring, thus altering surgical management. For example, bronchoscopy can detect the presence of associated complete tracheal rings or tracheomalacia. Immediate postprocedure intraoperative bronchoscopy allows the surgeon to assess the efficacy of the intervention. Adjunctive aortopexy or anterior tracheal suspension can be performed during the same operative procedure if persistent airway compromise is encountered.⁸⁸ Preoperative or intraoperative bronchoscopy alters management in approximately 3% to 5% of patients.⁸⁹

Angiography is rarely indicated for patients with vascular rings, but it may be necessary if coexistent coarctation of the aorta is suggested. In patients with right or left aortic arch and contralateral ligamentum, the

FIGURE 113-11 ■ Three-dimensional magnetic resonance imaging reconstructions demonstrating right aortic arch (RAA), aberrant left subclavian artery (LSCA) (A), and double aortic arch (B). DK, Diverticulum of Kommerell. (Compliments of Andrew Powell, MD, Children's Hospital Boston.)

presence of a ligamentum might not be demonstrated by noninvasive methods. In these cases, a rudimentary diverticulum at the insertion of the ligament into the aorta may be detected by angiography, suggesting the presence of the vascular ring.⁹⁰

Treatment

Controversy exists regarding indications for repair of the vascular ring. The presence of airway or esophageal symptoms corresponding with anatomic narrowing on imaging should prompt surgical treatment. In the asymptomatic patient, surgical treatment should be considered in patients with evidence of significant narrowing (>50%) by imaging, whereas patients with negligible anatomic narrowing can be managed safely by observation with serial imaging. Patients with pulmonary artery sling are likely to develop tracheal narrowing with time, and early operative intervention is recommended.

The options for surgical approach to a vascular ring include sternotomy, thoracotomy, or VATS. The optimal approach depends on the morphology of the arch anomaly and associated abnormalities (coarctation or complete tracheal rings) that require intervention. Regardless of the etiology of the vascular ring or the surgical approach, an important component of ring division is lysis of residual fibrotic tissue overlying the adventitia of the esophagus and trachea.

Double Aortic Arch

More than 85% of patients with double aortic arch display right dominance with atresia or hypoplasia of the left arch. Even when balanced arches or left dominance are present, division of the LAA is possible without development of significant obstruction to flow through the remaining right-sided arch. Measurement of upper and lower extremity blood pressures during test occlusion of the left arch can be used to predict adequacy of the right arch. If the right-sided arch is significantly hypoplastic or atretic, then division of the right aortic arch becomes necessary. Regardless of which arch requires division,

FIGURE 113-12 ■ Division of left ligamentum arteriosum in a patient with right aortic arch. Tethering attachments across the underlying esophagus must be divided to provide complete relief of obstruction in patients with double aortic arch or right aortic arch with left ligamentum.

surgery for double aortic arch can be performed through the left pleural space, using thoracotomy or VATS. The open approach is generally required for division of the right arch and may be preferable for division of a patent left arch. A ligamentum arteriosum or PDA is divided before further dissection. If this is not performed and only the left arch is divided, a vascular ring will persist. When atresia of the nondominant arch is present, division must be performed at the atretic segment to preserve blood flow to the branch vessels. Once the vascular ring has been divided, fibrous attachments tethering the trachea and the esophagus must be divided longitudinally to ensure relief of anatomic obstruction (Fig. 113-12).

Right Aortic Arch with Left Ligamentum Arteriosum

Division of the ligamentum arteriosum and underlying fibrous bands along the esophagus relieves tracheal and

esophageal compression (see [Figure 113-12](#)). Occasionally, the left ligamentum (and aberrant LSCA, if present) will arise from a diverticulum of Kommerell. Management of this diverticulum is controversial. Diverticular resection and repeated anastomosis of the aberrant LSCA to the left carotid artery avoids the risk of further dilation of the diverticulum and recurrent tracheoesophageal compression.⁹¹ Other options for management include plication and posterior diverticulopexy to the prevertebral fascia.

Circumflex Retroesophageal Aorta

The boundaries of the complete ring include the circumflex aorta, the pulmonary artery, and the ligamentum arteriosum or ductus arteriosus contralateral to the aortic arch, and division of the ring is simply performed by dividing the ligamentum. If the aberrant subclavian artery arises from a diverticulum, resection of the diverticulum and reimplantation of the subclavian artery is recommended. This is performed through a thoracotomy ipsilateral to the ligamentum. In some patients with circumflex aorta, simple division of the ligamentum and reimplantation of aberrant subclavian artery might not be sufficient to relieve the posterior esophageal compression. In these patients, aortic division and “uncrossing” by mobilization and rerouting of the descending aorta ipsilateral to the descending aorta relieves esophageal compression. Extra-anatomic reconstruction with division of the transverse aorta and ascending to descending prosthetic graft is another option.⁹² Coarctation and hypoplasia of the circumflex aorta (particularly right circumflex aorta) can occur, and they are treated with resection with reanastomosis or interposition graft.^{93,94}

Left Aortic Arch and Aberrant Right Subclavian Artery

Patients with a diagnosis of LAA and aberrant RSCA rarely experience airway compromise, and alternative causes of airway symptoms should be sought. In the rare patient with a right ligamentum, a complete vascular ring is formed, and division of the ligamentum provides relief of airway compression. For symptomatic esophageal compression, surgical treatment involves division of the subclavian artery at its origin from the aorta. This can be performed through a sternotomy or left thoracotomy approach. Reimplantation of the RSCA into the ascending aorta avoids the small risk of chronic upper extremity ischemia, but is controversial. If aneurysmal dilation of the aorta or proximal subclavian artery is encountered, one must be prepared to institute left heart or cardiopulmonary bypass and possibly hypothermic circulatory arrest during repair. Endovascular options for treatment have emerged, but the long-term results of this approach are still lacking.⁹⁵

Pulmonary Artery Sling

The repair of this anomaly is typically performed via median sternotomy, and consists of division of the LPA from the RPA and reimplantation into the main

pulmonary artery anterior to the trachea. Alternatively, the trachea can be divided and brought posterior to the pulmonary artery. The latter approach is useful if tracheal resection or reconstruction is necessary because of the presence of complete tracheal rings and tracheal stenosis. The decision to perform concomitant airway reconstruction depends on the degree of intrinsic airway abnormality, and it can be aided by performance of intraoperative bronchoscopy following release of the pulmonary artery sling. If concomitant airway surgery is required, the reconstruction with sliding tracheoplasty is the preferred procedure.⁹⁶ Cardiopulmonary bypass is essential if airway reconstruction is required. For LPA reimplantation alone, bypass is not essential but minimizes the hemodynamic burden on the right ventricle and allows unencumbered performance of the anastomosis. Immediate postoperative complications following repair of a pulmonary artery sling include persistent respiratory difficulties secondary to an abnormal airway, and long-term complications are seen in patients who require tracheal reconstruction during infancy.⁹⁷ Late stenosis of the LPA anastomosis occurs infrequently and is effectively treated with percutaneous balloon dilation.

Innominate Artery Compression

Children with suspected innominate artery compression syndrome should undergo thorough imaging and preoperative bronchoscopy to confirm anterior airway compression attributable to the innominate artery before proceeding with repair. Direct compression of the airway by the innominate artery or the aorta can be treated with thymectomy and innominate artery suspension through the right or left transpleural approach. Thymectomy is helpful when preoperative studies indicate the presence of a large thymus, which can exacerbate the posterior displacement of the innominate artery onto the anterior trachea. Innominate artery suspension can be performed through a right- or a left-sided approach, or through a partial sternotomy. The pericardial reflection at the base of the innominate artery is suspended to the posterior aspect of the sternum, thus lifting the innominate artery anteriorly. Improvements in symptoms and pulmonary function have been demonstrated following repair.^{98,99}

Prognosis

Low hospital mortality is expected following division of vascular ring. The proportion of patients experiencing improvement in respiratory symptoms following surgery ranges widely from 50% to 90%.¹⁰⁰⁻¹⁰² Recurrence of symptoms may be attributed to the presence of an enlarging Kommerell diverticulum, circumflex aorta, or underlying tracheobronchial malacia.¹⁰³ Management with resection of the diverticulum and primary reanastomosis of the LSCA into the left carotid artery, aortic “uncrossing” for circumflex aorta, or aortopexy and tracheopexy for trachea-broncho-malacia.^{103,104} Bronchoscopy at the time of vascular ring division or reoperation for residual compression provides feedback during surgical manipulation. The long-term results of vascular ring division are generally dependent on the degree of intrinsic airway

FIGURE 113-13 ■ Placement of ports in relationship to scapula during left video-assisted thoracoscopic surgery with the patient in the right decubitus position.

abnormality, such as tracheomalacia or complete tracheal rings. In one long-term analysis, follow-up surveys revealed that approximately half of the patients with preoperative breathing difficulties were symptom free at long-term follow-up, and the remaining patients described improvement in symptoms compared with preoperative status.¹⁰⁵ Younger age at operation and underlying genetic syndromes are risk factors for persistent symptoms. After repair of pulmonary artery sling, significant improvements in pulmonary function tests have been noted.¹⁰⁶

Complications

The most common cause of in-hospital morbidity relates to underlying airway abnormalities, and adequate pulmonary toilet must be maintained in the postoperative period. Patients undergoing pulmonary artery sling repair are at the highest risk for persistent airway instability and pulmonary insufficiency. Surgical complications related to the mediastinal dissection include recurrent laryngeal nerve injury, pneumothorax, chylothorax, and esophageal leak. Chylothorax is best managed by early reoperation for ligation of the injured lymphatic vessel, although percutaneous embolization of the thoracic duct is an effective alternative.¹⁰⁷

Surgical Approaches

The muscle-sparing thoracotomy, VATS, and sternotomy are the most commonly used approaches for repair of PDA, coarctation, and vascular rings. Sternotomy is the approach used if cardiopulmonary bypass is necessary (hypoplastic arch in addition to coarctation, calcified PDA in an adult). Sternotomy can provide security of cardiopulmonary bypass in case of unexpected vascular injury in a patient with unusual anatomy (PDA associated with ductal aneurysm). Although selective single-lung ventilation by means of a double-lumen endotracheal tube provides superior visualization in adults, a single-lumen endotracheal tube is sufficient to perform

procedures in most patients. For left-sided aortic arch, a left chest approach is preferred. The patient is placed in a right lateral decubitus position with a roll under the axilla to avoid nerve compression injury. A blood pressure cuff on the lower extremity allows intraoperative measurement of upper-lower extremity gradient, which is a crude but useful estimate of residual aortic obstruction. In the operating room, a pulse oximeter or blood pressure cuff should be placed on a lower extremity to confirm lower body perfusion after surgical manipulation of the descending aorta. Early identification and treatment of obstruction prevents subsequent morbidity and delay in treatment.

Thoracotomy

A posterolateral thoracotomy is performed by making an infrascapular incision parallel to the course of the underlying ribs. The latissimus muscle is divided, but the serratus anterior muscle is spared. For repair of coarctation or vascular ring, the fourth intercostal space is entered, and for PDA ligation the third interspace provides direct exposure. The pleura is opened for vascular ring and coarctation surgery, whereas an extrapleural or transpleural approach can be used for PDA ligation. With either approach, the pleura overlying the aorta is mobilized, and the recurrent laryngeal is identified and dissected away from the aorta. Complications related to the thoracotomy and dissection include recurrent laryngeal nerve injury, chylothorax, pneumothorax, and surgical site infections. Musculoskeletal deformities late after thoracotomy in children have become less frequent with the adoption of muscle-sparing techniques.¹⁰⁸

Video-Assisted Thoracoscopic Surgery

There are several different methods of VATS for division of vascular rings or patent ductus arteriosus. Our approach is to make four 3 mm incisions as shown in [Figure 113-13](#). Exposure of the aorta is provided by an

expandable lung retractor, and thoracoscopic instruments are used to perform the dissection, ligation, and division of atretic ligaments. Thoracoscopic division of a patent double aortic arch must be performed with a plan for vascular control (tourniquet, direct pressure, thoracotomy) should uncontrollable bleeding be encountered. Thoracoscopic division of vascular rings and PDA has not been shown to decrease operative times, postoperative pain, or hospital length of stay compared with the thoracotomy approach.¹⁰⁹

HISTORICAL CONSIDERATIONS

Ingenious and risky surgical corrections of atrial septal defect (ASD) predated cardiopulmonary bypass. The earliest closed approaches included a technique in which a straight needle with suture, guided by palpation, was passed blindly through the defect and both atria, and the free walls of the left and right atria were drawn together to obstruct the defect.¹ Bailey and colleagues described the “atrio-septo-pxy” consisting of a digital invagination of the atrial appendage through the defect with external suture attachment of the atrial tissue to the perimeter of the defect (Fig. 114-1A).² Tyge Sønnergaard devised a purse-string external suture closure of ASD by a near circumferential dissection around the defect in the plane

of the interatrial groove and a plication of its edges (see Fig. 114-1B).³

Semiopen techniques used before cardiopulmonary bypass became common practice included the “atrial well” technique, where a right atriotomy was formed, controlled by partial atrial clamping. A 15-cm tall, open-ended rubber cone was then attached to the atriotomy to produce an open column of blood in continuity with the beating heart. Working through the atrial well by palpation, the defect was closed by direct suture or patch. Regional intermittent heparinization prevented blood clotting within the well (see Fig. 114-1C).⁴

Lewis and Taufic reported the first successful open-heart ASD closure under direct visualization, using surface cooling and circulatory arrest by inflow occlusion in 1953.⁵

FIGURE 114-1 ■ Techniques for surgical atrial septal defect closure predating cardiopulmonary bypass. **A**, Atrio-septo-plexy. **B**, External purse-string suture closure. **C**, Atrial well technique. (**A**, From Bailey CP, Nichols HT, Bolton HE, et al: Surgical treatment of forty-six interatrial septal defects by atrio-septo-plexy. *Ann Surg* 140:805–820, 1954; **B**, from Sønndergaard T: Closure of atrial septal defects; report of three cases. *Acta Chir Scand* 107:492–498, 1954; **C**, from Barratt-Boyes BG, Ellis FH Jr, Kirklin JW: Technique for repair of atrial septal defect using the atrial well. *Surg Gynecol Obstet* 103:646–649, 1956.)

Further modification of this technique to include continuous coronary perfusion improved the safety of this and other early intracardiac procedures and represented a precursor to modern myocardial protection techniques.⁶

The modern era of cardiac surgery was heralded by the introduction of the pump oxygenator in 1953, and the earliest application of this technology was for ASD closure.⁷ Intracardiac repairs by inflow occlusion were not uniformly replaced by cardiopulmonary bypass techniques until 1960.

EMBRYOLOGY AND GENETICS

Formation of the Interatrial Septum

The embryonic common atrium undergoes partitioning by the formation of two parallel, overlapping septa, the septum primum and the septum secundum, starting in the fourth week of gestation.

The septum primum, emerging from the roof of the embryonic common atrium, begins the septation. The ostium primum, a gap between the septum primum and the atrial floor, almost closes by the completion of the septum primum. A de novo defect in the septum primum forms when a portion of its superior aspect resorbs, forming the ostium secundum.

The septum secundum, forming by the end of the sixth week of gestation, grows parallel to and immediately rightward of the septum primum, obliterating any remaining ostium primum, and circumscribing a central opening, the fossa ovalis.

In its final configuration, the atrial septum consists of the two layers, fused except for the overlapping, offset openings of the fossa ovalis and the ostium secundum. The free edge of the ostium secundum forms a flap valve covering the left side of the fossa ovalis, providing free right-to-left flow through the foramen ovale, until post-natal physiology closes the valve (Fig. 114-2). Conditions

impairing the competence of the valve, or abnormalities in the formation of its components, lead to a persistent interatrial communication.

Simultaneous with atrial septal formation, pulmonary vein connections with the primitive left atrium are forming. During the fourth week of gestation, the common pulmonary vein orifice forms from posterior invaginations of the sinus venosus segment into the mesenchyme of the primitive lung buds. The sinus venosus segment of the posterior common atrium forms where right and left omphalomesenteric and cardinal veins drain into the left and right sinus horns. An abnormal persistence of the right-sided anlage of the common pulmonary vein might be the embryologic basis for the development of abnormal connections of pulmonary veins to the right atrium, or partial anomalous pulmonary venous connection (PAPVC).⁸

Genetics

A familial predisposition to ASD is well documented. A study that included more than 18,000 subjects with congenital heart disease from a Danish population determined a recurrence risk for isolated secundum ASD of approximately 7%, a finding similar to prior studies.^{9–11}

Numerous genetic conditions and syndromes known for their extracardiac manifestations are also associated with ASD. Secundum ASD is the most common congenital cardiac defect associated with VACTERL (vertebral anomalies, anal atresia, cardiac defects, tracheal anomalies, esophageal atresia, renal anomalies, and limb anomalies). Genetic syndromes with associated ASD include Holt-Oram, Rubinstein-Taybi, Okimoto, and Townes-Brocks syndromes.¹² Trisomy 21 is associated with ASD either in isolation or as part of a constellation of endocardial cushion defects. Noonan syndrome is associated with ASD and pulmonary valve stenosis.¹³ DiGeorge syndrome (22q11.4 deletion) and Ellis-Van Creveld syndromes are associated with primum ASD. Additional

FIGURE 114-2 ■ Four-chamber sectional diagrams of the fetal heart with particular attention to the morphology of the forming interatrial septum and the foramen ovale. **A**, The early stages in the formation of the septum primum, from the superior aspect of the common atrium. **B**, As the septum primum grows toward the endocardial cushion, the ostium primum is defined. **C**, As the ostium primum closes, the ostium secundum forms by the resorption of the cephalad portions of the septum primum. **D**, The septum secundum begins to form rightward and parallel to the septum primum, obliterating the remaining ostium primum. **E** and **F**, The septum secundum circumscribes the foramen ovale, and the septum primum creates a flap valve permitting only right-to-left flow. AV, Atrioventricular; FO, foramen ovale. (Reproduced with permission from Patten BM: Developmental defects at the foramen ovale. *Am J Pathol* 14:135-161, 1938.)

specific genes implicated in familial forms of ASD include *GATA4*, *NKX2.5*,¹⁴ alpha-cardiac actin 1 (*ACTC*),¹⁵ alpha-myosin heavy chain (*MYH6*),¹⁶ and *MSX1*.¹⁷

The conduction system forms concurrently with atrial septation and PR prolongation can accompany ASD, in likely association with abnormalities of the *TBX5* transcription factor gene.¹⁸

Patent Foramen Ovale

The patent foramen ovale (PFO) denotes a failure of the septum primum and septum secundum to fuse. A failure of fusion results in either a valve-competent, “probe patent” PFO or valvular incompetence with or without an aneurysm of the septum primum component (Fig. 114-3A). Forces producing an enlarged foramen ovale or a deficient septum primum contribute to incompetence of the valve, a physiologically significant PFO, and transseptal shunting.

Secundum Atrial Septal Defect

The secundum defect lies within the bounds of the fossa ovalis, widely ranging in morphology from the slit-like PFO at the superior aspect of the fossa, to defects involving part or all of the remainder of the fossa, with a single or multiply fenestrated communication. Defects of various specific morphologies classified as secundum ASD can form as a result of underdevelopment of the septum secundum or a malformation of the septum primum resulting in incomplete coverage of the ostium secundum (see Fig. 114-3B).

Primum Atrial Septal Defect

The primum defect is a persistence of the ostium primum and is most commonly associated with an atrioventricular (AV) septal defect (see Fig. 114-3C). This lesion is discussed further in Chapter 116.

FIGURE 114-3 ■ The morphologic classification of atrial septal defects. **A**, Patent foramen ovale. **B**, Secundum atrial septal defect. **C**, Primum atrial septal defect. **D**, Superior sinus venosus defect. **E**, Coronary sinus interatrial defect. FO, Foramen ovale; IVC, inferior vena cava; SVC, superior vena cava; TV, tricuspid valve.

Sinus Venosus Defect

The sinus venosus interatrial defect is associated with a PAPVC. Ninety percent of PAPVCs are right-sided, 7% left-sided, and 2% bilateral. The most common subtype is right upper pulmonary vein-to-superior vena cava (SVC) connection, accounting for 74% of PAPVC cases, in usual association with sinus venosus ASD.¹⁹ The more common superior variant of sinus venosus defect is an interatrial communication lying posterior and superior to the true atrial septum, and the SVC overrides the defect. The right upper pulmonary veins, usually two or more, drain to the right atrium at the superior cavoatrial junction or enter the SVC directly (see Fig. 114-3D). In rare cases, they may enter the azygous vein as well. The SVC is commonly enlarged as it enters the right atrium.

The less common inferior sinus venosus defect is a communication inferior and posterior to the fossa ovalis with the right pulmonary veins entering the right atrium near the inferior cavoatrial junction. Although the sinus venosus ASD is remote from the fossa ovalis, a PFO or secundum ASD also may be present.

Atrial Septal Aneurysm

Redundant atrial septal tissue within the fossa ovalis with a respiratory excursion greater than 10 mm is termed an *atrial septal aneurysm* (ASA).²⁰ The ASA may occur with or without a PFO and has been implicated in the

formation of paradoxical embolus. ASA is present in 2% to 4% of the normal population, and 70% of cases are associated with a PFO.²¹

Coronary Sinus–Type Atrial Septal Defect

The uncommon coronary sinus–type ASD results from a complete or partial unroofing of the coronary sinus along its course through the floor of the left atrium. A communication of the coronary sinus with the left atrium results in an interatrial communication at the level of the coronary sinus ostium, the size of which is determined by the extent of unroofing and the size of the ostium (see Fig. 114-3E). Concomitant cardiac lesions occurring with coronary sinus ASD include ASDs within the fossa ovalis, persistent left-sided SVC, and pulmonary or tricuspid atresia. The rarity of coronary sinus defects, their tendency to elude echo diagnosis, and the finding that many elude even intraoperative recognition, underscore the importance of maintaining suspicion for this lesion when the degree of intracardiac shunt observed is inordinate for the known defect elsewhere.

Iatrogenic and Traumatic Atrial Septal Defect

Iatrogenic ASDs are found after 87% of catheter-based transseptal pulmonary vein isolation procedures. Most

are smaller than 1 mm in diameter and 96% resolve spontaneously, requiring no intervention.²² Rare cases of traumatic ASD after blunt or penetrating trauma have been described.²³

INCIDENCE AND NATURAL HISTORY

More than 60% of healthy full-term infants have a PFO identifiable on transthoracic echocardiogram.²⁴ With the postnatal fall in pulmonary resistance and rise in left ventricular end-diastolic pressure, the pressure in the left atrium exceeds that in the right atrium, and the flap valve consisting of septum primum closes the foramen ovale. Fibrous adhesions form in the first year of life to seal the interatrial communication in most cases. Spontaneous closure rates of PFO diagnosed in infancy are high—87% to 96% for those diagnosed in the first 12 months of life.²⁵ The overall incidence of persistent PFO in adulthood, deduced from autopsy specimens, is 27%. A PFO is present in one third of people younger than 29 years of age, one fourth of those 30 to 79 years, and one fifth of persons older than 80.²⁶

Secundum ASD occurs in 1.6 out of 1000 live births, second in prevalence only to ventricular septal defect (VSD). ASD accounts for 10% to 15% of congenital heart defects in children²⁷ and 20% to 40% of defects discovered in adults. Women are affected twice as often as men.²⁸ Maternal exposures associated with ASD in offspring include alcohol, hydantoin, valproic acid, and amphetamines. Infections and additional conditions associated with ASD include cytomegalovirus or rubella infection during pregnancy, diabetes, older maternal age, multigestational birth, and obesity. Low-birth-weight and premature infants have a higher prevalence of ASD than does the general population.²⁹⁻³¹

A significant number of ASDs close spontaneously within the first few years of life, but spontaneous closure after age 3 to 4 is rare.³² The likelihood of spontaneous closure is best predicted by the initial diameter of the secundum defect. Longitudinal data demonstrate that more than half of defects diagnosed in infancy and measuring 4 to 5 mm close spontaneously. Thirty percent regress in size to smaller than 3 mm. However, none close spontaneously when the defect measures larger than 10 mm at diagnosis.³³ Defects larger than 8 mm at diagnosis usually enlarge over time. If there is aneurysmal formation, sizes diminish regardless of whether they are larger than 8 mm.³⁴

In contrast to children with ASDs, most patients older than 40 years of age are symptomatic and have evidence of elevated pulmonary vascular resistance. If these patients are not treated, their average life expectancy is 40 to 50 years. Seventy-five percent die by age 50, and 90% die by 60 years of age.³⁵ Even the asymptomatic adult with ASD has a measurably diminished aerobic exercise capacity, which further declines with advancing age.³⁶ A 2008 European heart survey of 882 adults with isolated secundum ASD, including 505 unrepaired patients, demonstrated a precipitous rise in the prevalence of right ventricular dysfunction in unrepaired patients after 45 years of age. The degree of right ventricular volume

overload was the best predictor of reduced exercise capacity. A steady rise in the prevalence of pulmonary hypertension was observed in unrepaired patients after age 30. Findings support the suggestion that the magnitude of the intracardiac shunt may increase over time. Hemodynamically small defects tend more to remain stable and may not require closure.³⁷

Isolated ASD can predispose the patient to subacute bacterial endocarditis, although the actual incidence of endocarditis in this setting is rare. Scattered case reports describe atrial septal endocarditis in direct association with native ASD, ASD repaired by surgical or device closure, and by septal involvement of endocarditis that extends from other intracardiac structures. Risk of endocarditis from an unrepaired ASD is sufficiently low that antibiotic prophylaxis is not recommended, according to the latest American Heart Association guidelines. Incompletely repaired defects and those closed with prosthetic material or devices suspected of incomplete endothelialization are regarded as endocarditis risks, and do require antibiotic prophylaxis for dental or surgical procedures.³⁸

ASSOCIATED FEATURES

Isolated ASD in infancy and childhood is seldom symptomatic, even for large defects, and symptoms of congestive failure should prompt a careful effort to rule out additional associated abnormalities. Associated lesions found in the study of infants with ASD dying in the first year of life included left-to-right shunting lesions, such as VSD or patent ductus arteriosus (PDA); right-sided obstructive lesions, such as pulmonary stenosis; and left-sided obstructive lesions, such as aortic stenosis, mitral stenosis, or coarctation of the aorta. Necropsy data show that patients with VSD had an associated ASD in 18% of cases, those with left-sided obstruction had an associated ASD in 29% of cases, and those with right-sided obstructive lesions had ASD in 31% of cases.³⁹ These associations support the hypothesis that some secundum ASDs are acquired, driven by remote lesions that favor persistent atrial level shunting and atrial dilation, in turn leading to valvar incompetence at the fossa ovalis.

Mitral valve abnormalities have long been recognized as associated with ASD, although their associated incidence is uncommon. Mitral stenosis with pulmonary artery dilation in association with ASD, or Lutembacher syndrome, was perhaps a more frequent association found in the era when rheumatic heart disease was more prevalent, although nonrheumatic mitral stenosis is occasionally found in association with ASD.⁴⁰ A cleft anterior mitral leaflet, mitral prolapse, or regurgitation has also been reported in uncommon association with ASD. Mitral prolapse may be a result of septal distortion by right ventricular volume overload and a secondary effect on mitral valve geometry. As evidence in favor of this hypothesis, mitral prolapse has been shown to reverse after ASD closure.⁴¹

Tricuspid regurgitation in association with ASD is usually caused by annular dilation from the enlarged right ventricle, and it also reverses with ASD closure. The

most common additional cardiac anomalies associated with ASD include PAPVC, VSD, PDA, persistent left SVC, pulmonary valve stenosis, and branch pulmonary artery stenosis.⁴²

P wave prolongation associated with ASD may predispose the patient to the eventual development of atrial fibrillation. P wave duration may be shortened by ASD closure in younger adults, suggesting that the chronicity of atrial stretch is a contributing factor.⁴³ Closure of ASD in older adults does not affect this electrical pathophysiology and does not shorten preexistent P wave prolongation.⁴⁴ The presence of paroxysmal atrial fibrillation prior to ASD closure results in no shortening of P wave duration by closure.⁴⁵

HEMODYNAMICS AND PATHOPHYSIOLOGY

Left-to-Right Shunt

In early infancy, when pulmonary resistance is high, left and right ventricular compliances are similar, and net shunting through an ASD is typically slight. As the left ventricle matures, it becomes less compliant in diastole than the right, and left atrial pressure rises. This drives a left-to-right shunt at the atrial level in the presence of an ASD. With age, the disparity between systemic and pulmonary resistance, and in turn between left and right ventricular compliance, results in increased left-to-right shunting and advancing right ventricular volume loading. Over time, right ventricular volume load results in dilation and hypertrophy, eventually affecting the function of both ventricles. Atrial enlargement may contribute to the late incidence of atrial fibrillation. Right ventricular volume overload is noted to occur as a rule when ASDs are larger than 6 mm in diameter.⁴⁶

Volume-induced hypertrophy of the right ventricle produces a loss of coronary reserve and eventual impairment of right ventricular systolic and diastolic function. Left ventricular functional reserve is diminished by adulthood in most patients with ASD. Although left ventricular systolic function may be normal at rest, the left ventricle exhibits a subnormal diastolic dimension, and a loss of functional reserve at exercise. Mechanisms that account for left ventricular dysfunction include (1) septal displacement secondary to right ventricular dilation and hypertrophy and (2) systolic anterior movement of the mitral valve. In general, the functional loss in the left and right ventricles is normalized 6 months following ASD closure in children and young adults.⁴⁷

Pulmonary Vascular Disease

Pulmonary hypertension associated with an isolated ASD is rare in childhood, although 35% to 50% of patients with unrepaired ASD have elevated pulmonary resistance by age 40. The development of pulmonary vascular disease is not uniformly related to age or degree of shunting across the ASD. In contrast, patients with VSD predictably develop pulmonary hypertension earlier and more severely, subjected to similar left-to-right

shunting and elevated pulmonary blood flow. No explanation has been found for why shunts of similar volume from ASDs or VSDs, generating similar elevations in pulmonary blood flow, produce different patterns of pulmonary hypertension. In a study of 128 patients with ASD and pulmonary hypertension (all older than 18 years), one third demonstrated an elevation in pulmonary vascular resistance (PVR) before 20 years of age, one third between 20 and 40, and the remainder after 40 years of age.⁴⁸

Pulmonary hypertension can develop at an earlier age in premature infants and in children with Trisomy 21. Histopathologic evidence of increased preacinar and intra-acinar arterial muscularity in infants with ASD and pulmonary vascular disease suggests that the pulmonary vasculopathy is the primary disorder in the uncommon population with early pulmonary vascular disease. The ASD may be acquired as a consequence, or it may be incidentally associated.⁴⁹

Clinical Presentation

A great majority of ASDs are asymptomatic, and palpitations, atrial fibrillation, and congestive failure are late sequelae, uncommon in patients younger than 40 years of age. Occasional dyspnea on extreme exertion is observed even in children. Recurrent respiratory infection in the presence of a large ASD is not uncommon. Chylothorax has been reported as a presenting manifestation of ASD and is cured by ASD closure.⁵⁰

In rare cases, ASDs may be associated with cyanosis. Bidirectional shunting across the ASD without an elevation in the pulmonary resistance has been demonstrated as a source of cyanosis.⁵¹ An alternative anatomic source for cyanosis is a streaming of desaturated inferior vena cava (IVC) blood across the ASD, caused by a persistently enlarged eustachian valve or other venous drainage anomaly that directs blood flow into the left atrium.⁵² More ominously, cyanosis can develop in the setting of advanced irreversible pulmonary hypertension.

Additional clinical associations with PFO include stroke, migraine headache, high altitude pulmonary edema, and diver's decompression disease.⁵³

Diagnostics and Examination

Findings consistent with ASD at physical exam largely reflect the left-to-right shunting and elevated right ventricular volume and flow. A prominent right ventricle impulse is present, with a precordial right ventricular lift, leftward displacement of the apex, and possible left chest wall prominence.

Auscultatory findings include a systolic flow murmur heard over the left upper sternal border from elevated flow across the pulmonary valve, a split S2, fixed throughout the respiratory cycle, with a prominent pulmonary valve component. An apical mid-diastolic murmur, especially at inspiration, reflects increased flow across the tricuspid valve.

The chest X-ray demonstrates cardiomegaly with prominent pulmonary vascularity and a prominent pulmonary artery bulb.

The electrocardiogram in ASD shows right ventricular hypertrophy, lengthened PR interval, incomplete right bundle branch block, and an RSR pattern in V₁. Electrocardiographic criteria for right ventricular enlargement are found in more than 50% of young patients with a large ASD. A traditional teaching is that the secundum ASD is associated with right-axis deviation and incomplete right bundle branch block (rSR' pattern in right precordial leads), whereas the primum defect exhibits left-axis deviation with incomplete right bundle branch block. A normal preoperative electrocardiogram was found in only 6% of a study population of sinus venosus ASD.⁵⁴ Although some of these electrocardiographic findings are reported as useful in children, they are not sensitive diagnostic features in adults and are seldom referenced in an era when an echocardiographic diagnosis is sensitive, specific, and readily available.⁵⁵

Cardiac catheterization is similarly seldom used in the diagnosis of ASD, but, when performed, an SVC to right atrium O₂ saturation step-up is reflective of the left-to-right shunting at the atrial level. A pressure gradient, usually less than 25 mm Hg at peak, may be detected across the pulmonary valve that is physiologic, reflecting the elevated pulmonary blood flow. Echocardiography is the most common mode of diagnosis, capable of acquiring sufficient morphologic and physiologic data to obviate the need for catheterization in a great majority of cases.

Transthoracic echocardiography with color Doppler flow mapping is accepted as the most accurate modality of ASD diagnosis in children, capable of detecting smaller intracardiac shunts compared with two-dimensional echocardiography alone. Small defects and defects in obscure locations, such as coronary sinus defects and some sinus venosus defects, may remain difficult to image by echocardiogram. High-resolution computed tomography (CT) and cardiac magnetic resonance imaging (MRI) have been used to image some interatrial defects that have eluded adequate echocardiographic characterization. MRI is particularly useful in imaging partial anomalous pulmonary venous structures that may lie adjacent to the airways and lung, where air interface interferes with the echocardiographic image resolution (Fig. 114-4).⁵⁶

MANAGEMENT OF ATRIAL SEPTAL DEFECT AND PATENT FORAMEN OVALE

Indications and Contraindications for Atrial Septal Defect Closure

The patients benefiting most from ASD closure are those at risk for developing pulmonary hypertension, but once pulmonary hypertension is present, surgical risk increases. This principle is the basis for the recommendation to close all significant ASDs.⁵⁷ Elective closure of ASD is generally recommended when the ratio of pulmonary to systemic blood flow (Q_p:Q_s) is 1.5:1 or greater. Ideally, ASD closure should be performed at age 2 to 5 years, before exercise capacity changes, while chest wall compliance is optimal, and before school age. An echo diagnosis

FIGURE 114-4 ■ Three-dimensional cardiac magnetic resonance image of a heart (posterior view), showing right upper pulmonary veins anomalously entering the superior vena cava (SVC), cephalad to the atriocaval junction in a patient with superior sinus venosus atrial septal defect. (Courtesy David Parra, MD, Vanderbilt Children's Heart Institute.)

of a significant defect with right ventricular volume overload is common and is a sufficient indication to close an ASD. Long-term follow-up data after surgical ASD closure show survival equal to the normal population when repair is performed early in life, with an age-related diminution in survival when closure is delayed. The 27-year survival for those repaired after 40 years of age is only 40%.⁵⁸

A small hemodynamically insignificant ASD, without cardiomegaly, does not warrant closure. Pregnancy is a relative contraindication to closure, with closure safely delayed until after delivery. Severe left ventricular failure is a contraindication to ASD closure.

Advanced pulmonary hypertension is a contraindication to ASD closure. It is important to consider that, in a high flow state, with a large Q_p:Q_s, high pulmonary artery pressure may not represent fixed pulmonary hypertension. As a general guideline, irreversible pulmonary hypertension is characterized by a PVR 8 to 12 Wood unit X m², with Q_p:Q_s less than 1.2:1, despite aggressive vasodilator challenge.

Moderate pulmonary hypertension with a reactive component is not a contraindication to ASD closure, although pulmonary hypertension may progress in these patients regardless of closure. In cases of severe pulmonary hypertension, a fenestrated ASD closure may be successfully performed, depending on the degree of reversibility and PVR. Guidelines for inoperability are largely based on VSD data. Generally, the PVR must fall below 7 Wood unit X m² with vasodilator therapy at cardiac catheterization for ASD closure risk to be less than prohibitive.⁵⁹ Vasodilators used at cardiac catheterization to determine the reversible component of pulmonary hypertension include hyperoxia, inhaled nitric oxide, and intravenous prostacycline (Flolan). Chronic preparatory vasodilator therapy with sildenafil has been successfully used to convert inoperable pulmonary hypertension to operable.⁶⁰

Patent Foramen Ovale Management

Indications for Patent Foramen Ovale Closure

The aggressive expansion of catheter-based therapies for PFO has resulted in a proliferation of clinical studies and case reports to reexamine indications for PFO closure. Although a subject of some continuing controversy, there are presently insufficient data to support the medical, surgical, or device treatment of the incidentally diagnosed, hemodynamically insignificant PFO. Adverse events attributed to the presence of a PFO or associated ASA include embolic stroke or peripheral embolus, brain abscess, gas embolization in diver's decompression illness, platypnea-orthodeoxia syndrome, migraine headache, and exacerbated hypoxia in settings of pulmonary embolus or elevated right heart pressures following a right ventricle infarct.⁶¹ Indications for PFO closure in these settings are also controversial and are discussed later.

Patent Foramen Ovale and Stroke

The associations of PFO with stroke are complicated, age dependent, and not fully resolved. When discussing the risk of stroke, it is important to distinguish first ischemic stroke from cryptogenic stroke (stroke with no known underlying causal condition) and from recurrent stroke.

An association between PFO and cryptogenic stroke is accepted in the younger population, an age group for whom stroke is rare in general. An association between cryptogenic stroke and the presence of PFO is strong for patients younger than 55 years of age, and the association is even stronger if ASA, with or without PFO, is present.⁶² Prospective studies corroborate this trend but with no statistical significance, leaving some room for controversy.⁵³

Causality after 55 years of age is less clear, complicated by various other sources for ischemic stroke that occur concurrently in the older population. Although the association is not as strong as that of the younger population, PFO independently remains associated with cryptogenic stroke in older patients.⁶³

There appears to be no relationship between size of interatrial shunt and risk of recurrent stroke.^{62,64}

Although there is a convincing association between cryptogenic stroke and PFO, the presence of PFO as predictor of first or recurrent stroke is less well established. Whereas the presence of untreated PFO predicts a 2.3% risk of recurrent cerebrovascular event by 4 years after the initial event, the presence of ASA with PFO predicts a 15.2% recurrence risk at 4 years.⁶⁵ Antiplatelet therapy following stroke mitigates the risk for recurrent stroke. For stroke victims with PFO and no ASA younger than 55 years of age, the annual risk of recurrent stroke while taking aspirin is only 1% to 2%.

Strategies for treatment of PFO after an ischemic event include PFO closure or medical management with aspirin or Coumadin. Various reports support the superiority of either anticoagulation therapy or mechanical closure of PFO for patients who have suffered cryptogenic stroke.

Obstacles remain to fully understanding the relationship of PFO to stroke and to determining the optimum treatment strategy. Antiplatelet therapy routinely applied after device closure further confuses the distinction between the effects of mechanical versus medical treatment. Systematic review fails to demonstrate advantages of closure versus anticoagulant therapy for the prevention of recurrent cryptogenic stroke in the presence of PFO, although there are data to suggest that the benefit of device closure may be device specific and that treatment may need to be individualized.⁶⁶⁻⁶⁸

Generally accepted practice guidelines suggest a treatment strategy as follows:

1. Aspirin alone for any asymptomatic patients with PFO or ASA. Risk of stroke in this population is 1%/yr or less.
2. Coumadin for patients with PFO and a hypercoagulable state, history of stroke, transient ischemic attack (TIA) or deep vein thrombosis (DVT) preceding stroke. Coumadin imposes a 2.2%/yr risk of bleeding complication, 0.2% fatal. PFO closure for this population may be indicated.
3. PFO closure for patients younger than 60 years old who have suffered cryptogenic stroke if the PFO is associated with ASA (4%/yr risk of stroke, even on aspirin), with DVT before stroke, or with TIA or stroke while on antithrombotic therapy.⁶⁹

Patent Foramen Ovale and Migraine

Although PFO may be present in more migraine sufferers than in the general population, especially for those with migraine accompanied by an aura, a clear association is not well established. Migraine cure or improvement has been reported in many patients undergoing closure of PFO, but the association of PFO closure and migraine improvement may be affected by placebo effect, periprocedural anticoagulation therapy, short follow-up, and device complications. The only randomized clinical trial of PFO closure for severe migraine has failed to demonstrate a positive effect.⁷⁰ Closure of PFO cannot firmly be recommended for the treatment of migraine at present, although additional randomized clinical trials are under way.^{53,71}

Patent Foramen Ovale and Diver's Decompression Illness

Bubbles in the left heart are documented by echocardiogram to demonstrate diver's decompression illness in association with PFO. Underwater pressure and its effects on ventilation elevate the pulmonary resistance, reducing left ventricular preload while increasing right-sided pressures, and favoring right-to-left shunting across the PFO. The overall risk of diver's decompression illness with PFO is low, with 5 events per 10,000 divers, but these odds are fivefold above the odds for those without PFO.

In a prospective, nonrandomized, controlled trial of PFO closure among divers with PFO, long-term follow-up demonstrated an apparent advantage to PFO closure in preventing symptomatic decompression injury and asymptomatic neurologic findings on MRI.⁷² These

findings suggest consideration of PFO closure for frequent divers, although firm evidence to support screening or prophylactic PFO closure is lacking.³⁵

Catheter-Based Treatment

King and Mills reported the first catheter-delivered ASD closure in 1976, using a double umbrella device and a 23 Fr delivery catheter. The large-delivery catheter and complex delivery method prevented widespread use.⁷³ In 1983, Rashkind introduced a self-expanding patch device that attached to the septum with small barbed hooks. The device was unfortunately hindered by the inability for repositioning and its risk of inadvertent attachment to other structures within the heart.⁷⁴ The concept of a self-expanding patch led to the development of the Lock Clamshell device—a double disc, self-expanding device that could be delivered through an 11 Fr delivery sheath. First reported in 1990, this was the first device to receive widespread use.⁷⁵ Device arm fracture resulted in its eventual redesign. In 1993, Das reported the use of the Angel Wings device—a self-expanding, double patch device with a conjoint central ring acting as a waist. Although its use was limited by its rigid frame, its sharp edges, and difficulty with its retrieval, its circular central waist demonstrated the benefit of a self-centering device.⁷⁶ Over the subsequent 20 years, numerous devices have been designed and investigated for the treatment of secundum ASDs. The two devices currently approved by the Food and Drug Administration (FDA) in the United States are the Amplatzer septal occluder (St. Jude Medical, St. Paul, MN)⁷⁷ and the Helex septal occluder (Gore & Associates, Flagstaff, AZ).⁷⁶ Devices currently available outside the United States include the Gore septal occluder (W.L. Gore & Associates, Flagstaff, AZ)⁷⁸; the Ultrasept ASD occluder, which is a modification of the Atriosept device (Cardia, Inc., Eagan, MN)⁷⁹; Occlutech Figulla ASD occluder (Occlutech, Jena, Germany)⁸⁰; the Cardio-Fix (CSO) ASD occluder (Starway Medical Technology, Inc., Beijing, China)⁸¹; and the Cera ASD occluder (Lifetech Scientific Co., Ltd., Shenzhen, China).⁸²

Most ASDs today are closed by catheter-based devices. The Amplatzer and Helex occluders are the most commonly used approved devices at this time. A national sampling of community hospital practices found a 58-fold increase in the annual number of devices placed from 2002 to 2004, whereas surgical closure rates remained constant.⁸³ The success rate and morbidity are almost equal when comparing device closure with surgical closure. Current published studies comparing the two approaches with anatomically similar defects show a device success rate of 80% to 95.7% and a surgical closure success rate of 95% to 100%, although the success of device closures continues to evolve. Complications requiring treatment (defined to include anemia, arrhythmia requiring minor treatment, post pericardotomy syndrome, pericardial or pleural effusion, transfusion, fever, wound complication) occur in up to 8% of device closures and 23% to 24% of surgical closures, and mean length of hospital stay is 1 day in the device group versus 3.4 days in the surgical group.^{84,85} Continual advances in the hardware and experience with device closures are

improving the success rate of these catheter-based approaches.

Anatomic determinants that prohibit device closure remain the major indications for surgical ASD closure in the current era. Defects unsuitable for device closure include those that have failed attempted device closure, common atria or those without sufficient septal rim to engage the device, and sinus venosus defects for which device closure would threaten obstruction of pulmonary veins, IVC, or SVC. Anterior-inferior septal deficiency can result in device interference with the tricuspid valve, mitral valve, or coronary sinus. Individual deficient septal rims, although originally constituting contraindication to device closure, no longer are absolute contraindications but may reduce success rates.⁸⁶ The largest Amplatzer septal occlusion device presently available in the United States is 38 mm, and defects exceeding this size require surgical closure. Multiple defects can be closed with multiple devices, although the cost of multiple device closures may exceed the cost of surgery. Determinants of the limitations to device closure are under evolution as devices and their delivery systems continue to undergo refinements.

Pooled data from multiple sources estimate that major complications of device closure of ASD and PFO occur in 1.4% of cases and minor complications in 1.4%.⁸⁷ Early major procedural complications of device closure include device embolization; cardiac tamponade; stroke or TIA; retroperitoneal hematoma; thrombosis; device erosion; obstruction of the IVC, coronary sinus, or pulmonary vein; and tricuspid or mitral insufficiency. Non-cardiac complications include iliac vein dissection, retroperitoneal or groin hematoma, and leg ischemia. Minor complications include minor vascular complications, arrhythmia, transient ST-segment elevation, percutaneously retrieved device embolization, pericardial effusion, device malposition not requiring surgery, and pulmonary edema. Late complications include device-related death, cerebrovascular events, device thrombosis or malposition, embolization, erosion, aortoatrial fistula, arrhythmia, device fracture, pericardial effusion, endocarditis, and nickel toxicity.⁸⁷

As experience with devices matures, their indications and limits are better defined. Evidence suggests that a higher incidence of complications is expected for patients who weigh less than 15 kg and that waiting for somatic growth may be preferable.⁸⁸ A fluoroscopically guided catheter-based approach raises concern for radiation exposure; this consideration is eliminated when echo-guided ASD closure is used.^{89,90} A large defect or a large device is a risk factor for AV block.⁹¹ Careful avoidance of device oversizing, especially in patients with a deficient aortic rim, may prevent erosion or perforation.^{92,93} Absent posterior-inferior rims may increase risk of dislodgement, and patients with this anatomy might more safely be served by surgery.⁹⁴

A recent 20-year outcome comparison of device versus surgical treatment of comparable ASDs shows no significant differences in survival, functional capacity, arrhythmia, or late embolic stroke between methods of closure, supporting a transcatheter approach for defects amenable to device closure.⁹⁵

Surgical Treatment

Secundum Atrial Septal Defect and Patent Foramen Ovale

The standard surgical incision for the repair of ASD is partial or complete median sternotomy. A portion of the anterior pericardium is preserved for use as a patch. Various other materials have been used as a patch, including bovine pericardium and polytetrafluoroethylene (PTFE), but autologous pericardium is a compliant, durable, and cost-efficacious choice. Bicaval venous cannulation, mild hypothermia, and antegrade cardioplegia are used to provide a still, blood-free field through which to expose the interatrial septum via right atriotomy. A careful examination of the interatrial septum ensures the correct identification of the margins of the defect. The SVC and IVC are identified, with special attention to any structures that might represent partial anomalous pulmonary venous return (PAPVR) to the right atrium or vena cavae. The eustachian valve is identified to avoid the error of baffling the IVC to the left atrium. The coronary sinus is identified and protected from inclusion in the suture line. A determination is made to close the defect primarily where there is sufficient septum primum tissue, or with a patch. Care is exercised to place sutures firmly into surrounding tissue but without interfering with the adjacent noncoronary sinus of the aorta superiorly, the tricuspid or mitral valves anteriorly, the coronary sinus and AV node inferoanteriorly, the IVC and right lower pulmonary vein orifice inferiorly and posteriorly, or the right upper pulmonary vein and SVC superoposteriorly (Fig. 114-5). When the defect is closed primarily, adequate redundant tissue must be present to ensure that no tension will be placed on the repair once the heart is filled and beating.

Sinus Venosus Atrial Septal Defect with Partial Anomalous Pulmonary Venous Return

The most common variant of sinus venosus ASD is the superior, when the right upper pulmonary vein drains anomalously to the right atrium or SVC. A single intra-atrial patch can be positioned to baffle the pulmonary vein through the septal defect into the left atrium in many cases. Care is exercised to place the SVC incision remote from the sinoatrial node. The single-patch technique may predispose to SVC narrowing, as the baffle occupies space within the SVC lumen.⁹⁶ A two-patch approach enlarges the SVC to accommodate the baffle.

When one or more pulmonary veins connect to the SVC too cephalad to permit simple baffling, an adjunctive patch plasty of the lateral SVC must be carried out. Anticipating such geometry, an atriotomy can be planned at the lateral base of the SVC, so that septal and caval patch plasties can be placed through a single atriotomy, extended as far as necessary onto the SVC (Fig. 114-6). ASD enlargement may also be needed to ensure an unobstructed baffle.

The Warden procedure, described in 1984,⁹⁷ consists of transection of the SVC cephalad to the connection of

FIGURE 114-5 ■ Surgical anatomy of the interatrial septum with atrial septal defect. AVN, Atrioventricular node; CS, coronary sinus; EV, eustachian valve; IVC, inferior vena cava; RAA, right atrial appendage; RLPV, right lower pulmonary vein; RUPV, right upper pulmonary vein; SVC, superior vena cava; TV, tricuspid valve.

the anomalous pulmonary vein, thereby committing the atriocaval junction to pulmonary venous blood flow exclusively. An intra-atrial patch baffles the atriocaval junction to the left atrium, through a preexistent or created ASD. The transected SVC is then reimplanted into the right atrial appendage by direct anastomosis (Fig. 114-7). A tensionless SVC anastomosis is imperative to the success of the SVC reimplantation, and patch augmentation is sometimes necessary. Special care must be taken to resect all trabecular muscle in the atrial appendage that might impair SVC flow through the reimplantation site.

A retrospective examination of 54 patients with superior sinus venosus ASD and PAPVR treated at Children's Memorial Hospital showed a 55% incidence of the loss of sinus rhythm. These patients had a low atrial or junctional rhythm that did not increase normally with exercise. These data support consideration of the Warden procedure for the correction of all superior sinus venosus ASDs when the right upper pulmonary veins enter the SVC.⁹⁸

Primum Atrial Septal Defect

Characterized by the absence of any septal tissue between the AV valves, the primum ASD closure requires that the patch be sutured directly to mitral or tricuspid tissue, avoiding the subjacent ventricular septum and the His bundle, and sometimes leaving the coronary sinus on the left atrial side to avoid the AV node. An examination of the mitral valve and closure of the associated cleft is

FIGURE 114-6 ■ Repair of superior sinus venosus atrial septal defect. **A**, A lateral atriotomy provides exposure to the anomalous right upper pulmonary vein. **B**, A pericardial baffle is constructed to direct right upper pulmonary vein flow to the left atrium, through a created or enlarged secundum defect. **C**, Completed intra-atrial baffle. **D**, A patch plasty of the atriotomy extends sufficiently cephalad on the superior vena cava to avert caval obstruction. IVC, Inferior vena cava; RUPV, right upper pulmonary vein(s); SVC, superior vena cava.

indicated, even in the absence of mitral regurgitation. Care is taken to avoid creating mitral stenosis. The primum defect is discussed fully with AV septal defects.

Minimally Invasive Approaches

Various alternatives to the median sternotomy have been described for the repair of ASD. An inframammary or axillary incision with thoracotomy provides exposure of the right atrium with a scar that is more easily concealed than the full median sternotomy. The subxiphoid “min-isternotomy” or partial lower sternotomy can be performed through small vertical or transverse inframammary incisions, and cannulation through the incision rather than peripherally.⁹⁹ Experience continues to expand with methods that use even smaller incisions, femoral cannulation, and video or robotic assistance.¹⁰⁰⁻¹⁰² These alternative approaches may confer a cosmetic advantage over the standard midline incision and median sternotomy, although to date it has been difficult to demonstrate objective advantages in cardiac physiology, pulmonary physiology, pain, length of anesthesia, length of hospital stay, or cost.¹⁰³

Complications of Surgery

Early complications following the surgical closure of ASD include patch dehiscence, thromboembolism, and arrhythmia such as heart block, sinus node dysfunction, and atrial fibrillation or flutter. Early postoperative arrhythmia following ASD repair may predict an eventual need for pacemaker.¹⁰⁴ The incidence of residual shunt after surgical closure is negligibly small.⁸⁴ Residual right-to-left shunting can occur with incomplete closure, with undiagnosed additional defects, and when ASD closure mistakenly engages the eustachian valve, baffling the IVC inadvertently to the left atrium and resulting in cyanosis. In the setting of pulmonary hypertension, ASD closure can result in systemic venous hypertension, right ventricular failure, or low cardiac output and can require a return to cardiopulmonary bypass to fenestrate the closure.

An examination of late outcome 27 to 32 years after surgical repair of ASD showed that age at the time of repair is an independent risk factor for late complications. Late cardiac failure, stroke, and atrial fibrillation are more frequent when the patient’s age at repair is older

FIGURE 114-7 ■ The Warden procedure. **A**, Cutaway view of the right atrium, showing the relationship of the displaced right upper pulmonary vein (RUPV) and its distance from the atrial septal defect and left atrium. **B**, Superior vena cava (SVC) transected above the abnormal pulmonary vein. IVC, Inferior vena cava.

than 25 years.⁵⁸ Independent risk factors for the development of atrial fibrillation with ASD, repaired or not, include age older than 25 years, left atrial enlargement, and mitral or tricuspid regurgitation.¹⁰⁵ Thirty to forty percent of patients older than 40 who exhibit atrial fibrillation after ASD repair may have an embolic event within 10 years of ASD repair, and systemic anticoagulation is a consideration in this group.¹⁰⁶

Reported complications of thoracotomy approaches include phrenic nerve palsy, lung herniation, cardiac herniation, scoliosis, and breast or chest muscle deformity.^{107,108}

OUTCOME

Physiology of Atrial Septal Defect Closure

Subtle changes in exercise performance in ASD patients can be measured even in childhood. An abnormal ventilatory threshold during submaximal exercise returns to normal by 6 months after repair of ASD in patients younger than 5 years of age but remains subnormal for patients repaired older than 5 years.¹⁰⁹ Most patients older than 5 years old at the time of repair have at least

some residual right ventricle dilation and abnormal septal wall motion after ASD closure, not predicted by preoperative shunt or ASD size.¹¹⁰ The clinical significance of this finding is unclear. These data may further support a strategy of ASD closure before school age.

Adults

Although the adult with ASD benefits by improvement in exercise physiology and reduction of right ventricle dilation after closure of ASD, the improvements are less pronounced with advancing age.^{57,111} There is a clear survival advantage and a reduction in the incidence of cardiovascular events for ASD closure in patients younger than 40, when compared with expectant management.¹¹² Some controversy remains as to the best treatment strategy in the older adult population.

Regardless of the presence of symptoms, the incidence of right heart enlargement in adults decreases after surgical or device closure of ASD, although right atrial enlargement may persist, proportional to the age at repair.¹¹³⁻¹¹⁵ Although younger adults demonstrate an improved $\text{VO}_{2\text{max}}$ within months of ASD closure, patients older than 40 years who undergo repair may take years to show improvement. A low preoperative peak oxygen uptake has been demonstrated in adults with ASD,

increasing by 4 months after repair, fully normalizing by 10 years after surgical ASD repair.^{113,116} Prior to ASD closure, more than 60% of patients older than 40 years of age are New York Heart Association (NYHA) class III to IV, whereas after ASD closure, more than 80% are NYHA class I to II.¹¹⁷ Patients older than 60 show functional class improvement, immediate and late reduction in pulmonary artery pressure, and improved 5- and 10-year survival after ASD closure in comparison with expectant management.^{118,119} These data support a strategy of ASD closure regardless of age for most patients. Independent risk factors for prolonged hospital stay in adults after ASD closure include preoperative atrial fibrillation, larger ASD, older age at operation, and longer cardiopulmonary bypass time.¹²⁰ A higher incidence of postclosure acute left ventricular failure and pulmonary congestion occurs with larger ASDs and with older age at repair.¹²¹

Arrhythmia

If ASD closure is performed in childhood, the incidence of early or late atrial tachyarrhythmia or sinus node dysfunction is rare.¹²² The prevalence of atrial flutter or fibrillation may already be rising in the unrepaired young teenager, and prevalence is clearly increased after age 40.^{14,44,58}

A significant incidence of postoperative atrial fibrillation in the adult has given consideration to performing a Cox-Maze arrhythmia ablation procedure concurrent with ASD closure for patients older than 40 years of age. No randomized data support performing a Cox-Maze procedure, but observational studies show benefit in adult patients undergoing ASD closure who have preoperative atrial fibrillation or flutter.¹²³ A right atrial Maze procedure alone may be ineffective in restoring and maintaining sinus rhythm after ASD closure, and higher success is achieved by performing a biatrial Maze procedure.¹²⁴

COR TRIATRIATUM

Cor triatriatum sinistrum, one of the rarest cardiac anomalies, comprises 0.1% of congenital heart defects. In the classic form, described by Church in 1868, cor triatriatum is a separation of the pulmonary veins from the left atrium by a fibromuscular membrane. The anatomic elements of the left atrium, including the atrial appendage, are all ventral to the membrane, and the communication between pulmonary veins and left atrium is restricted to an orifice in the membrane.¹²⁵ The membrane can contain single or multiple fenestrations and can also communicate with the right atrium directly through an ASD, or indirectly, through an ascending or descending vertical vein. A variety of classifications have been devised to characterize the various drainage patterns of the pulmonary venous chamber into the heart (Fig. 114-8).

A subdivided right atrium, sometimes referred to as cor triatriatum dexter, is a membranous division of the right atrium, unrelated to cor triatriatum sinistrum. Cor

triatriatum dexter forms from a persistence of the right sinus venosus valve, which normally regresses by 12 weeks of embryonic age.¹²⁶ The subdividing right atrial membrane can take on a variety of forms, ranging from a prominent Chiari network to a full septation that subdivides the right atrium or prolapses through the tricuspid valve, even to the extent that right ventricular outflow is obstructed.¹²⁷

Embryology

The cor triatriatum sinistrum membrane contains elements of the embryonic common pulmonary vein and the wall of the left atrium. Van Praagh suggests that the dorsal chamber is the embryonic common pulmonary vein and that entrapment of the left atrial ostium of the common pulmonary vein by sinus venosus tissue results in a failure of the normal course of incorporation into the ventral left atrial chamber during the fifth embryonic week.¹²⁸ Van Praagh's explanation is the most widely accepted. Other theories postulate a malformation of the septum primum or an incomplete incorporation of the common pulmonary vein into the left atrium.¹²⁹⁻¹³¹

The partially obstructed pulmonary venous chamber of cor triatriatum may form an ascending or descending vertical vein decompressing it into the systemic venous circulation at the IVC or SVC, similar to that of supracardiac or infracardiac total anomalous pulmonary venous connection. The degree of connectedness between the chambers determines the degree of obstruction.

Associated Abnormalities

Combinations of cor triatriatum and partial anomalous pulmonary venous drainage have been described, with normally draining left- or right-sided veins to the proper left atrium and contralateral veins connecting to a dorsal venous chamber. Associated partial anomalous pulmonary venous drainage to a vertical vein or to the coronary sinus has been described.¹³² Cor triatriatum has a high association with the presence of a left SVC, an association theorized to be involved in the pathogenesis of cor triatriatum.¹³¹

Other intracardiac anomalies associated with cor triatriatum sinistrum include pulmonary stenosis, Ebstein anomaly, tricuspid anomalies, VSD, tetralogy of Fallot, AV septal defect, and hypoplastic left heart.^{133,134}

Clinical Presentation

The clinical presentation of cor triatriatum is usually in infancy and is manifested by symptoms and signs of pulmonary venous congestion and pulmonary hypertension. Poor growth, episodic exacerbations of pulmonary edema, and frequent pulmonary infections are common. The severity of the presentation is dependent on the degree of pulmonary venous obstruction. Those patients with a communication to the right atrium generally have a milder progression of symptoms, as the pulmonary venous chamber decompresses into the right atrium. Patients presenting later in life may additionally have syncope, hemoptysis, atrial fibrillation, embolic

FIGURE 114-8 ■ The subtypes of cor triatriatum. **A**, The classic cor triatriatum, with the common pulmonary chamber draining through a restrictive membrane perforation, into the true left atrium. **B**, Communications between the common pulmonary venous chamber and both right and left atria. **C**, A vertical decompressing vein from the common pulmonary venous chamber to the innominate vein. **D**, Pulmonary venous effluent entering the right atrium through a direct communication, and the left atrium through a secundum atrial septal defect. **E**, An infracardiac vertical decompressing vein from the pulmonary venous chamber to the systemic venous system. AC, Accessory chamber; CPV, common pulmonary vein; IVC, inferior vena cava; LA, left atrium; LInnV, left innominate vein; LPV, left pulmonary vein; LV, left ventricle; PV, pulmonary vein; RA, right atrium; RPV, right pulmonary vein; RV, right ventricle; SVC, superior vena cava; vv, vertical vein. (Reproduced with permission from Hammon JW, Bender HW: Major anomalies of pulmonary and thoracic systemic veins. In Sabiston DC, Spencer FC, editors: *Surgery of the chest*, ed 6, Philadelphia, 1995, WB Saunders, p 1422.)

complications, and right heart failure.¹³⁵ The progression of symptoms in the adult with cor triatriatum may be the result of the development of mitral regurgitation. Calcification of the membrane is found in adults and can account for a narrowing of the perforation in the membrane, with a resultant exacerbation of symptoms. In a study of 31 necropsy specimens from untreated patients prior to 1960, the mean age at death was 3.3 months if the ostial diameter was smaller than 3 mm and 16 years for an ostial diameter larger than 3 mm.¹³⁶ Patients presenting as adults may exhibit progressive dyspnea and palpitations as presenting symptoms.

The physical exam is remarkable for congested lungs and a prominent second pulmonary sound on auscultation. Findings in patients presenting late with longstanding pulmonary hypertension and right heart failure include liver enlargement and jugular venous distention with a V wave. A systolic murmur at the left sternal border may be present.

The electrocardiogram demonstrates peaked P waves, suggesting right atrial enlargement. Right-axis

deviation and voltage are consistent with right ventricular enlargement.

The chest radiograph shows cardiomegaly consistent with right ventricular enlargement, prominent pulmonary artery, and vascular markings.

The diagnosis of cor triatriatum is typically made by echocardiogram, and cardiac catheterization is seldom necessary. Findings at cardiac catheterization include a gradient from pulmonary capillary wedge pressure to left atrium, pulmonary hypertension, venous phase angiographic imaging of an upper chamber, prolonged pulmonary transit time, differential opacification of upper chamber and left atrium, and an occasional linear definition of the membrane. In rare cases, thrombus may occur proximal to the membrane and present as a left atrial mass.

Pathophysiology

In the anatomic subtype in which the orifice of the membrane communicates exclusively with the left atrium, the

physiology of cor triatriatum is similar to that of mitral stenosis, with pulmonary congestion and/or edema depending on the degree of restriction at the membrane. For the subtypes with communication to the right atrium, a convoluted pathway of pulmonary venous flow delivers pulmonary venous effluent to the right atrium and then back to the left atrium through an interatrial communication below the membrane. Restricted filling of the left heart, low cardiac output, and pulmonary edema result, dependent on the degree of restriction along the pathway to the left atrium.

Pulmonary vein obstruction from cor triatriatum has been demonstrated to produce progressive medial thickening and intimal fibrosis in pulmonary veins and arteries, and lymphangiectasia, although neither as early nor as severe as is the progression of pulmonary vascular disease in VSD. The cellular intimal proliferation and advanced irreversible vascular changes characteristic of VSD or other left-to-right shunting lesions are not seen with pulmonary venous obstruction, and reversibility is the rule.¹³⁷

When an interatrial communication exists between the proximal chamber and the right atrium, a left-to-right shunt exists. When a communication exists between the right atrium and the underfilled left atrial chamber, a right-to-left shunt can occur.

Treatment and Outcome

The surgical repair of cor triatriatum is performed with bicaval venous cannulation, moderate hypothermia, and cardioplegic arrest. An examination of the surface anatomy of the heart often confirms the presence of a dilated pulmonary venous chamber behind the heart. The repair is typically performed through a right atriotomy and a subsequent incision into the left atrium across the interatrial septum. Caution is exercised to identify the mitral valve and protect it from injury during the resection of the membrane. Time taken to fully define the membrane prevents injury to adjacent structures, notably the mitral valve. The membrane is widely excised, so as to leave no flow gradient from the pulmonary vein orifices to the mitral inflow region of the left atrium. A careful external examination of the heart exposes any ascending or descending venous structures for ligation.

Cor triatriatum repair has excellent outcomes, with expected mortality of less than 2% of cases. Reintervention for recurrent obstruction is rare.¹³³

A concomitant Maze procedure has been described for the treatment of adults with cor triatriatum and atrial fibrillation.¹³⁸

Although the standard approach includes a complete surgical resection of the obstructing membrane, a percutaneous balloon dilation of cor triatriatum membranes by a transseptal approach has been reported.¹³⁹

ETIOLOGY

Normal embryologic development of the pulmonary venous system involves creation of a connection between the left atrium and the pulmonary venous plexus, and subsequent regression of systemic-to-pulmonary venous connections. Inappropriate connection of the pulmonary venous system to the systemic venous system is termed *anomalous pulmonary venous drainage*.

As part of normal embryologic development, the lungs are derived from buds arising from the primitive foregut. During the initial stages of pulmonary development (25 to 27 days' gestation), the pulmonary venous drainage is through the cardinal and umbilical-vitelline venous system (systemic veins). During the later stages of development (27 to 29 days' gestation), an outpouching of the common atrium forms to the leftward of the developing septal primum.¹ The structure, termed the common pulmonary vein, primordial pulmonary vein, or pulmonary pit, extends and bifurcates into the pulmonary venous

plexus and establishes venous drainage of the developing lung buds at 28 to 30 days' gestation (Fig. 115-1). Thereafter, the connection between the lung buds and the systemic venous system regresses, leaving the developing lungs with direct drainage to the left atrium.

Human genetic studies of kindreds with total anomalous pulmonary venous drainage showed an autosomal-dominant inheritance with incomplete penetrance and variable expression with involvement of genetic loci located in the human chromosome 4q12.² During heart morphogenesis, an avascular zone forms between the caudal primitive vascular structures (that will become part of the systemic vein circulation) and the pulmonary vein plexus, which arises from the lung.³ Disruption of this avascular zone and of the patterning of the pulmonary vein may be the primary developmental anomaly in the genesis of total anomalous pulmonary connection. In mice, a secreted repellent guidance molecule, semaphorin 3d, is located in the avascular zone and plays a key role in the correct patterning of the pulmonary vein connection to the left atrium (Fig. 115-2). Deficiency of

FIGURE 115-1 ■ Lung buds arise from the primitive foregut with systemic venous drainage during early embryologic development. At later stages, an outpouching from the common atrium extends and bifurcates into the pulmonary venous plexus to establish drainage to the atrium, followed by regression of the systemic venous drainage. (Modified from Jonas RA, Smolinsky A, Mayer JE, et al: Obstructed pulmonary venous drainage with total anomalous pulmonary venous connection to the coronary sinus. *Am J Cardiol* 59:431–435, 1987.)

semaphorin 3d is associated with anomalous connection of pulmonary veins with both atria or the coronary sinus. The mechanism suggested is based on the lack of repulsion guidance that leads to a broad domain of abnormal endothelial sprouts from the lung buds which may persist when blood flow through the connection begins (Fig. 115-3). In preliminary studies in humans with anomalous pulmonary venous connection, specific mutations in the gene sequence for semaphorin 3d have been identified.⁴

Anomalous pulmonary venous drainage can result from failure of fusion between the left atrial outpouching and the pulmonary venous plexus, or from malposition of the relationship between the atrial outpouching and the development of the atrial septum. If all the pulmonary veins maintain an anomalous connection to a single systemic venous site, the lesion is termed *total anomalous pulmonary venous drainage*. If all the pulmonary veins drain anomalously to multiple discrete systemic veins, the lesion is called *mixed total anomalous pulmonary venous drainage*. If one to three pulmonary veins drain via an anomalous pathway and at least one pulmonary vein drains to the left atrium, the lesion is termed *partial anomalous pulmonary venous drainage*.

PARTIAL ANOMALOUS PULMONARY VENOUS DRAINAGE

Anatomy

Partial anomalous pulmonary venous drainage is characterized by a failure of one to three of the pulmonary veins

to connect with the left atrium during fetal development. Typically, the pulmonary vein has an abnormal connection to the superior vena cava near the cavoatrial junction. More than 80% of patients have associated congenital heart defects, the most common of which is an atrial septal defect. A minority of patients (18%) have an intact atrial septum.⁵ Most commonly, a combination of right upper and middle lobe pulmonary veins drain to the superior vena caval–right atrial junction (Fig. 115-4). Less commonly, isolated anomalous right upper lobe venous drainage is present. Least commonly, the entire right lung drains via an anomalous vein into the right atrium.⁵ Other less common sites of anomalous venous drainage include the inferior vena cava (e.g., as part of the scimitar syndrome), the left-sided superior vena cava, and the innominate vein. The left pulmonary veins rarely can also have an anomalous drainage to the systemic venous circulation as isolated disease.⁶

Presentation

Patients are often asymptomatic and display a murmur noted on routine examination that is caused by increased flow across the pulmonary valve. A split and prominent second heart sound is also present. Symptomatic patients display the sequelae of a left-to-right shunt, including decreased exercise tolerance and poor growth. Patients are not cyanotic unless they have developed pulmonary hypertension as a late manifestation of a large left-to-right shunt. In such patients, Eisenmenger syndrome is characterized by the reversal of the shunt from right to left in association with an atrial septal defect.

Pathophysiology

The dominant hemodynamic abnormality is related to the left-to-right shunt imposed by pulmonary venous drainage into the right atrium. In the absence of an atrial septal defect, the left-to-right shunt is limited by the amount of flow in the anomalous pulmonary vein. In contrast, an associated atrial septal defect adds potential for increased left-to-right shunting at the atrial level. Increased right-sided flow can lead to right ventricular dilation, tricuspid insufficiency, and supraventricular arrhythmias.

Surgical Repair

The goal of surgical therapy is to divert the anomalous pulmonary venous effluent to the left atrium in an unobstructed fashion. In the presence of a sinus venosus atrial septal defect and anomalous right upper pulmonary veins, the flow is diverted with a baffle constructed along the edge of the sinus venosus atrial septal defect. The defect may have to be enlarged to create an unobstructed pathway to the left atrium. In the absence of an atrial septal defect (i.e., the atrial septum is intact), an atrial septal defect must be created in the region of the fossa ovalis with extension in the region of the limbus and a similar baffle constructed to divert flow from the anomalous pulmonary vein to the newly created atrial septal defect.

FIGURE 115-2 ■ Mice heart comparison between Semaphorin3d^{-/-} type and control. Anterior views of (A) adult control and (B) Semaphorin3d^{-/-} hearts. Severe cardiomegaly is shown in the mutants (B) because of right atrial (RA) and right ventricular (RV) dilation. In mutant mouse pulmonary veins (PV) enter the coronary sinus (CS; in B, left image). In control mice (A), pulmonary veins (PV) enter the left atrium (LA) as normal. Scale bars (in panels A–E and G) = 1 mm. LU, Lung; LV, left ventricle. (Modified from Degenhardt K, Singh MK, Aghajanian H, et al: Semaphorin 3d signaling defects are associated with anomalous pulmonary venous connections. *Nat Med* 19:760–765, 2013.)

Planning the Superior Vena Caval Cannulation

Careful review of the anatomy by preoperative echocardiography, computed tomography, or magnetic resonance imaging⁷ is the single most important component

in developing an operative plan. Definition of the pulmonary venous anatomy and associated defects allows assessment of options for cannulation techniques and surgical approaches. This is especially important in preparation for partial anomalous pulmonary venous drainage, because the location of the anomalous pulmonary venous

FIGURE 115-3 ■ Model showing the role of Sema3d in pulmonary vein patterning. Normally (*left*) Sema3d is expressed between the heart and the developing pulmonary vasculature where it repels endothelial cells to prevent the formation of anomalous connections. Deficiency of Sema3d (*right*) allows endothelial cells to enter this region and form anomalous vascular connections. CS, Coronary sinus; LA, left atrium; PV, pulmonary veins; RA, right atrium. (Modified from Degenhardt K, Singh MK, Aghajanian H, et al: Semaphorin 3d signaling defects are associated with anomalous pulmonary venous connections. *Nat Med* 19:760–765, 2013.)

FIGURE 115-4 ■ A contrast-enhanced magnetic resonance three-dimensional angiogram seen from right anterior projection shows an anomalous connection of the right upper and middle pulmonary vein draining into the superior vena cava (arrow). The right lower pulmonary vein normally drains into the left atrium. (Modified from Vyas HV, Greenberg SB, Krishnamurthy R: MR imaging and CT evaluation of congenital pulmonary vein abnormalities in neonates and infants. *Radiographics* 32:87–98, 2012.)

drainage determines the feasibility of a minimally invasive approach and placement of venous cannulas. A common clinical scenario involves an anomalous right upper pulmonary vein inserting high into the superior vena cava, at or above the level of the pulmonary artery. Options for control of the superior vena cava include a high cannulation of the superior vena cava, cannulation of the innominate vein, or percutaneous cannulation via the internal jugular vein with vacuum-assisted venous drainage. A minimally invasive approach through a lower midline partial sternal split can be difficult when a high insertion of an anomalous pulmonary vein is present. In this case a right posterior lateral minithoracotomy can be used as a minimally invasive approach to achieve better access to the high pulmonary veins. The cannulation strategy for this approach includes percutaneous cannulation of the internal jugular vein and direct surgical cannulation of the right femoral vein and artery. The use of peripheral cannulation augmented with vacuum assisted venous drainage is helpful.⁸ Limitations to the use of this approach are: patient's weight less than 20 kg and femoral vein or artery anomalies. During cardiopulmonary bypass, monitoring of right leg near-infrared spectroscopy is suggested. Near-infrared spectroscopy saturations less than 30% suggest that distal leg perfusion is insufficient. In patients with small femoral arteries, the use of a graft sewn to the femoral artery in end-to-side fashion can be helpful to avoid problems with distal leg perfusion.⁹

A final technique to consider is the use of a straight venous cannula in the right atrial appendage, which can be directed into the superior vena cava. After snaring the cava around the cannula (cephalad to the anomalous pulmonary vein insertion), an atrial incision allows access to the origin of the anomalous pulmonary vein from within the atrium. Although this technique is easily accomplished with a minimally invasive lower midline partial sternal split, working around the cannula through the right atrial–superior vena caval junction can be challenging.

Before initiation of cardiopulmonary bypass (CPB), the location of the pulmonary veins is confirmed. Drainage to the superior vena cava requires dissection of the lateral margin of the superior vena cava to identify all pulmonary vein branches. During dissection of the superior vena cava and right pulmonary veins particular attention is needed to avoid injury to the right phrenic nerve. Frequently, multiple branches drain into the vena cava through a large confluence. The source of the veins is not always clear, and any systemic veins draining into the region must be identified. When the source of the pulmonary venous drainage is not clearly defined, needle aspiration can be used to determine the oxygen saturation of the effluent, and then the systemic veins can be distinguished from the pulmonary veins.

After heparinization, cannulation, and initiation of normothermic CPB, the aorta is clamped and blood cardioplegic arrest is obtained. It is often helpful to place a vent into the left atrium for later de-airing. A lateral right atriotomy is made and the atrium is explored to identify any additional anomalies (Fig. 115-5). If the atrial septum is intact, an atrial septal defect is created by incising the region of the foramen ovale and extending the incision

FIGURE 115-5 ■ **A**, After initiation of cardiopulmonary bypass and cardioplegic arrest, a lateral right atrial incision is made (*dashed line*). The *stippled area* represents the approximate location of the sinoatrial node. **B**, The orifice of the anomalous pulmonary veins and the intact atrial septum are exposed. A secundum atrial septal defect is created by excising the septum primum in the region of the limbus, with care taken to avoid potential injury to the conduction system by keeping clear of the triangle of Koch. **C**, The limbus can be resected cephalad to increase the diameter of the atrial septal orifice. **D**, A glutaraldehyde-treated autologous pericardial patch is sutured in place along the rim of the newly created defect, thereby creating a tunnel from the pulmonary vein orifice to the left atrium. **E**, The patch is deliberately longer than necessary to reach the pulmonary vein orifice, and the redundant portion is left unattached as the suture line is extended across the edge of the divided pulmonary vein–atrial edge. The redundant portion of the patch is then folded anteriorly to augment the diameter of the superior cavoatrial junction, thereby preventing obstruction of the superior vena cava.

across the limbus in the direction of the anomalous pulmonary vein. Resection in the region of the limbus allows enlargement of the newly created atrial septal defect. Injury to the sinus node artery can occur when creating the atrial septal defect in patients whose artery courses through the superior portion of the intra-atrial septum. Enlargement of the sinus venosus defect might be necessary if it is too small to divert the anomalous pulmonary veins to the left atrium. Typically, a glutaraldehyde-treated pericardial patch can be used to create a baffle, so that pulmonary venous blood flows beneath the baffle and through the atrial septal defect into the left atrium.

Systemic venous blood from the superior vena cava must pass to the right atrium over the pulmonary vein–to–left atrial baffle without obstruction. If the origin of the pulmonary vein was high in the superior vena cava, the baffle must be constructed carefully to avoid obstruction to flow on either side of the baffle. A longitudinal incision in the lateral aspect of the superior vena cava allows the baffle construction to be better visualized. Placement of the incision on the lateral aspect of the superior vena cava is important to diminish the risk of injury to the sinus node. Closure of the superior vena cava incision with a generous patch to augment the

superior vena cava diameter can be used to prevent stenosis of the superior cavoatrial junction.

Alternatively, a new anastomosis between the superior vena cava and the right atrial appendage is established by dividing the superior vena cava cephalad to the anomalous pulmonary venous entry and translocating the cephalad end of the superior vena cava to the right atrial appendage (Warden technique). The divided cardiac end of the superior vena cava (bearing the anomalous pulmonary venous connection) is closed, and a baffle is created from the orifice of the superior vena cava to the newly created atrial septal defect.^{5,10} By creating a new superior vena caval–right atrial junction, this procedure eliminates the need to partition the superior vena cava with a baffle dividing the systemic and pulmonary venous flow paths. This approach can be particularly helpful in infants and small children with a high insertion of an anomalous pulmonary vein into the superior vena cava.

Results

Early and long-term outcomes for patients after repair are excellent. In children, closure of an associated atrial septal defect almost eliminates the risk of late development of atrial arrhythmias. However, in adults, closure of the atrial septal defect is associated with persistent risk of development of atrial arrhythmias.¹¹ Although extrapolation of these data for atrial septal defect closure to patients with partial anomalous pulmonary venous drainage and intact atrial septum has not been specifically validated, it seems reasonable to conclude that early removal of a left-to-right shunt associated with right ventricular overload is appropriate. In fact, surgical closure of the sinus venosus atrial septal defect at an older age is associated with increased risk of mortality, adverse events, and poor functional outcomes.¹²

Pertinent complications after repair of partial anomalous pulmonary venous drainage include stenosis of the superior vena cava or the anomalous pulmonary vein,¹³ residual atrial septal defects, and atrial arrhythmias or sinus node dysfunction (or both).¹⁴ Failure to include all pulmonary veins in the newly constructed baffle to the left atrium can result in a residual left-to-right shunt. However, incorporation of a systemic vein into the newly constructed baffle results in a residual right-to-left shunt. Finally, injury to the sinus node or sinus node artery can lead to the requirement for pacemaker insertion in patients with severe sinus node dysfunction.¹⁴

SCIMITAR SYNDROME

Scimitar syndrome is an unusual congenital anomaly that is manifested by partial anomalous pulmonary venous drainage of the right lung to the inferior vena cava; it is often associated with hypoplasia of the right lung, dextrocardia, systemic pulmonary arterial supply from the abdominal aorta to the lower lobe of the right lung, and bronchial abnormalities. Other commonly associated anomalies include atrial septal defect, aortic coarctation, and a left-sided superior vena cava.^{15,16} The morphology of the anomalous pulmonary venous drainage to the right

FIGURE 115-6 ■ Contrast-enhanced magnetic resonance angiogram shows the scimitar vein draining most of the right pulmonary venous blood flow into the inferior vena cava (arrow). The scimitar vein has severe stenosis at its junction with the inferior vena cava.

lower lobe creates a characteristic appearance to the right-sided heart border suggestive of a Turkish sword, hence the term *scimitar syndrome* (Fig. 115-6). The right-sided pulmonary veins drain to the inferior portions of the right atrium, the inferior vena caval–right atrial junction, or, more commonly, the inferior vena cava below the diaphragm. Stenosis can occur in 10% to 20% of scimitar veins at their junction to the inferior vena cava.^{16,17}

The presentation of patients with scimitar syndrome can be variable and depends on the severity of the associated lesions. There are generally two forms of clinical presentation in scimitar syndrome: (1) an infantile form with significant symptoms, morbidity, and mortality and (2) a form with mild symptoms seen in children or adults. At the most benign end of the spectrum, patients can display an asymptomatic flow murmur on physical examination as a result of increased pulmonary blood flow secondary to the left-to-right shunt caused by the anomalous pulmonary venous drainage to the inferior vena cava. At the most severe end of the spectrum, infants can exhibit symptoms of severe congestive heart failure, failure to thrive, tachypnea, and occasionally cyanosis. Infantile pulmonary artery pressures are often elevated (e.g., >40% of the systemic pressure), with a ratio of pulmonary blood flow (Qp) to systemic blood flow (Qs), or Qp/Qs, of up to 2:1.¹⁵

Surgical Management

The management strategy for patients with scimitar syndrome is determined by the degree of right lung hypoplasia, the presence of aortopulmonary sources of blood

flow to the right lung, and the location and pattern of the right-sided pulmonary venous drainage. The degree of right lung hypoplasia is an important determinant of the likelihood of salvaging a functional right lung, and in cases of severe hypoplasia, a right pneumonectomy has been advocated.¹⁸ In cases with less severe hypoplasia, attention is turned to correction of the pulmonary venous drainage patterns, control of aortopulmonary sources of blood flow, and correction of associated anomalies. Control of the aortopulmonary sources of blood flow can be achieved with coil embolization in the catheterization laboratory or with ligation in the operating room.¹⁹

Surgical repair of the pulmonary venous drainage is designed to create unobstructed flow from the anomalous pulmonary vein to the left atrium. To accomplish this repair, a direct surgical approach is to place a long baffle in the lumen of the inferior vena cava to channel the anomalous pulmonary vein effluent to the right atrium, and then through an atrial septal defect to the left atrium (originally described by Zubiate and Kay in 1962).²⁰ It can be challenging to create an unobstructed baffle when the anomalous pulmonary venous connection is relatively caudad in the inferior vena cava. To construct a partitioning baffle, a period of circulatory arrest is typically necessary to secure a baffle between the pulmonary vein orifice and left atrium that allows unobstructed pulmonary vein flow without restricting flow in the inferior vena cava or in nearby hepatic veins.

When partitioning the inferior vena cava between the systemic and pulmonary venous flow paths, a right atrial incision can be carried down to the level of the anomalous pulmonary vein orifice, and the orifice is augmented with a patch of autologous pericardium if stenosis is present. The baffle is then constructed in the lumen of the inferior vena cava, and, if necessary, the inferior vena cava diameter can be augmented with a patch to ensure that there is no residual obstruction in the vena cava. This technique has a relatively high incidence of late stenosis, presumably because of the length of the intracaval baffle and because the blood must pass through a nearly 180-degree turn as it travels caudad toward the inferior vena cava and then cephalad up through the baffle to the atrial septal defect.^{16,18}

A second approach is to divide the anomalous pulmonary vein and reimplant it at a convenient location in the right atrium and then create a baffle to divert flow to the left atrium through an atrial septal incision or atrial septal defect if present.^{16,21} This approach provides a shorter, more direct pathway for the pulmonary venous effluent. It is difficult to use this approach, however, when the anomalous pulmonary vein courses in the posterior portion of the lung and necessitates a great deal of augmentation to create an anastomosis with the atrium. When the pulmonary vein passes through the posterior mediastinum and the right lung is relatively hypoplastic, Huddleston and associates¹⁸ recommend pneumonectomy because of the high incidence of late stenosis with reimplantation techniques. As further justification of pneumonectomy in this setting, Huddleston and colleagues point out that the left lung has typically undergone some compensatory growth. Furthermore, perfusion scans typically demonstrate diminished pulmonary blood

flow to the right lung in patients with scimitar syndrome.¹⁵ Calhoun and Mee²² described an alternative surgical approach for this entity, in which the inferior vena cava is transected under deep hypothermic circulatory arrest and divided into posterior (the anomalous pulmonary vein channel) and anterior (inferior vena cava and hepatic vein) compartments with a pericardial patch. An incision is made on the inferior aspect of the left atrium and carried to the atrial septum. The posterior compartment of the inferior vena cava is sutured to the left atriotomy, and the pericardial patch is used to close the atrial septal defect. The anterior compartment of the inferior vena cava is anastomosed to the right atrium. This approach connects the anomalous pulmonary vein to the left atrium at a relatively gentle angle. Brown and coworkers¹⁷ reported favorable results with direct anastomosis of the anomalous pulmonary vein to the left atrium via right thoracotomy without the use of CPB.

Results and Complications

Survival after complete repair (embolization or ligation of anomalous pulmonary arterial flow with correction of the anomalous pulmonary venous return) is anticipated in older children and adults. In recent series, 5-year survival rates have reached 100%, although a significant incidence of late pulmonary vein obstruction remains. In the infantile form of the lesion, however, hospital mortality is higher and depends on the degree of lung hypoplasia and the presence of pulmonary hypertension.¹⁵ Even with a technically perfect repair, blood flow to the right lung often remains diminished. The left-to-right shunt, however, is eliminated. Pulmonary venous obstruction is a prevalent late finding in many series and may be related to the surgical techniques used. Long pulmonary venous pathways through the inferior vena cava with acute angulation may predispose to stenosis. Recent reports using direct reimplantation techniques have demonstrated minimal rates of postoperative stenosis in small series of patients.¹⁷ Pneumonectomy remains an option in patients with persistently compromised pulmonary blood flow resulting from pulmonary hypertension or pulmonary venous obstruction.¹⁸

TOTAL ANOMALOUS PULMONARY VENOUS DRAINAGE

Total anomalous pulmonary venous drainage is a condition in which all the pulmonary venous effluent from the lungs drains to the systemic venous system, creating a large left-to-right shunt. This entity accounts for 1% to 3% of all congenital heart malformations, with an incidence of 7.1 per 100,000 live births.²³ A right-to-left shunt must be present to allow blood to reach the left ventricle and thereby contribute to systemic cardiac output. Commonly, this shunt is at the atrial level as an atrial septal defect or patent foramen ovale. Less commonly, the shunt may be present as a ventricular septal defect. The absence of a shunt is incompatible with survival, and the magnitude of the shunt determines the systemic cardiac output.

Anatomy

Although well palliated in utero, infants with total anomalous pulmonary venous drainage have abnormalities in the pulmonary vascular system. There is often hypertrophy of the media of the pulmonary veins and arteries, intimal fibrous thickening of the pulmonary veins, and lymphangiectasia. These findings are accentuated in patients with pulmonary hypertension and evidence of pulmonary venous obstruction.²⁴ The various types of total anomalous pulmonary venous drainage are classified by the site of connection to the systemic venous system.

Supracardiac Anatomy

Supracardiac drainage is the most common anatomic variant, occurring in 45% to 55% of patients with total anomalous pulmonary venous drainage.^{23,25} The venous connection is typically through a pulmonary venous confluence behind the left atrium to a connecting vein (often termed a vertical vein) to the innominate vein. Other sites of pulmonary–systemic connection can be to a left- or right-sided superior vena cava.²³

Cardiac Anatomy

The pulmonary–systemic venous connection can be present at the cardiac level in 15% to 20% of patients.^{23,25} In this setting, the pulmonary veins typically drain to a pulmonary venous confluence behind the left atrium. The confluence then drains into the coronary sinus or, less commonly, to the right atrium. In some patients, the right- and left-sided pulmonary veins converge into a short vertical vein before draining into the coronary sinus. The latter variant may be more susceptible to late obstruction.^{25,26}

Infracardiac Anatomy

The systemic–pulmonary venous connection is present at the infracardiac level in 15% to 26% of patients.^{23,25} In this setting, the pulmonary veins drain to a confluence behind the left atrium, which drains via a descending vertical vein to the portal vein, to the ductus venosus (Fig. 115-7) or directly to the inferior vena cava. This subset displays obstruction in the pulmonary venous circuit in the majority of patients.

FIGURE 115-7 ■ **A** and **B**, Angiogram shows the infracardiac total anomalous pulmonary venous drainage (*asterisk*) draining in a stenotic vertical vein (VV). **C**, Stent deployment in the stenotic vertical vein during balloon inflation. **D** and **E**, Different projection of the stent implanted. **F**, Final result shows no obstructed flow returning from the pulmonary veins to the vertical vein. (Modified from Chaturvedi RR, Van Arsdell GS, Jacques F, et al: Delayed repair of right atrial isomerism with obstructed total anomalous pulmonary venous drainage by hybrid stent insertion between the left-sided atrium and pulmonary venous confluence. *J Thorac Cardiovasc Surg* 144:271–273, 2012.)

Mixed Anatomy

Mixed-type total anomalous pulmonary venous drainage accounts for 5% to 10% of patients.^{23,25} The most common mode (46%) of mixed-type total anomalous pulmonary venous drainage consists of bilateral and asymmetrical connections, with three pulmonary veins typically draining to a common site and one pulmonary vein to a remote site.²⁷ The second most common mode (29%) is bilateral and symmetrical connections, with separate anomalous connections of all veins from each lung forming confluences and then connecting to the systemic veins at separate sites. The third group, which accounts for 18%, has a common confluence to which all pulmonary veins drain, and then the confluence itself drains to the systemic veins at separate sites. Sites of connection can be at the supracardiac, cardiac, and infracardiac levels.

Presentation

Patients without significant pulmonary venous obstruction present in infancy or early childhood with signs and symptoms related to the presence of a large left-to-right shunt. These patients have dyspnea, poor feeding, and poor growth. They may have cyanosis on examination, but this manifestation is usually mild. Other findings include a second heart sound that is split and a systolic flow murmur caused by increased flow across the pulmonary valve.

Patients with high-grade pulmonary venous obstruction present in the neonatal period with cyanosis, respiratory distress, and poor growth. On examination, the infant is tachypneic and cyanotic and has poor systemic perfusion. The second heart sound is prominent and split as a result of pulmonary arterial hypertension. Obstruction in the pulmonary venous pathway in patients with total anomalous pulmonary venous drainage constitutes a surgical emergency. Medical measures to stabilize and resuscitate the patient include intubation, ventilation with 100% oxygen, hyperventilation, correction of pH, and inotropic support. These medical measures are minimally effective. Administration of prostaglandin E₁ has been reported to open the ductus venosus in an attempt to decompress the pulmonary veins in patients with infracardiac total anomalous pulmonary venous drainage and obstruction.²⁸ Catheter-based techniques to place a stent in the obstructed pulmonary venous confluence have been reported to relieve obstruction and to allow resuscitation of the patient in preparation for surgical repair.²⁹

Pathophysiology

The hemodynamic abnormality, in patients with total anomalous pulmonary venous drainage, is related to the complete diversion of pulmonary venous blood away from the left atrium to a systemic vein. Consequently, the most important anatomic factors in determining the clinical status of the patient include the presence and location of a right-to-left shunt, and the presence or absence of obstruction in the pulmonary venous circuit.

Because pulmonary venous blood is diverted from the left atrium, blood cannot reach the left ventricle in the absence of a right-to-left shunt. Therefore, to sustain life, a right-to-left shunt must be present. Most commonly, a patent foramen ovale or atrial septal defect is present to allow entry of blood into the left atrium and then to the left ventricle for systemic output. The cardiac output of the patient is therefore limited by the amount of blood that can cross the atrial septum. Thus, the characteristics of the obligatory right-to-left shunt determine the systemic cardiac output.

A second important anatomic factor determining the clinical status of the patient is the presence or absence of obstruction in the pulmonary venous pathway. When obstruction is present, egress of blood from the lungs is limited, resulting in pulmonary venous congestion and impairment of oxygenation. This can lead to life-threatening cyanosis in neonates. In addition to deficits in oxygenation and pulmonary blood flow, restriction at the level of the atrial septal defect reduces systemic cardiac output and further exacerbates the patient's precarious clinical status.

In patients with supracardiac anomalous pulmonary venous drainage, obstruction can occur in the ascending vertical vein connecting the pulmonary venous confluence to the innominate vein. In this situation, the passage of the vertical vein between the left pulmonary artery and the left bronchus can cause compression in the vertical vein. As the egress of blood from the lungs is restricted, the pulmonary artery pressure rises, causing further distention of the pulmonary artery and further compression of the vertical vein. This can create a repeating cycle of progressive pulmonary venous obstruction. Obstruction also can occur at the site of the connection between the pulmonary venous confluence and the systemic vein. This is a common feature of infracardiac total anomalous pulmonary venous drainage.

Diagnostic Techniques

Arterial blood gas sampling is useful in resuscitation of a neonate with obstruction and total anomalous pulmonary venous drainage. Often, severe metabolic acidosis and mild hypoxemia are seen.

Chest Radiography

The appearance of the lung fields on chest radiographs is determined by the presence or absence of obstruction to pulmonary venous drainage. In patients without obstruction, pulmonary vascularity is increased because of the large left-to-right shunt created by drainage of pulmonary venous return into the right side of the heart. In patients with obstruction, the lung fields may be extremely congested because of the obstruction of blood egress from the pulmonary veins and the left-to-right shunt. A prominence of the pulmonary artery shadow and the right atrium silhouette often exists. In supracardiac drainage, the prominence of the upper mediastinal silhouette can create the classic "snowman" or figure-eight appearance.

Echocardiography

Echocardiography is the study of choice in diagnosing total anomalous pulmonary venous drainage. The pulmonary venous confluence, pulmonary veins, and connection to the systemic venous system can typically be defined, allowing an expeditious and noninvasive diagnosis in critically ill infants, as well as in asymptomatic children. Consequently, echocardiography has largely replaced angiography as the principal diagnostic study in patients with total anomalous pulmonary venous drainage. Echocardiography also can offer important prognostic data. Jenkins and colleagues³⁰ correlated operative survival to the size of the pulmonary venous confluence and the sum of the pulmonary venous diameters (Fig. 115-8).

Fetal echocardiography can diagnose total anomalous pulmonary venous drainage and potential obstruction of the pulmonary venous pathways.³¹ Fetal diagnosis of total anomalous pulmonary venous drainage is of particular importance if the patient has prominent obstruction in the pulmonary venous pathway, because the patient requires immediate medical and surgical intervention after birth. The sensitivity of fetal echocardiography, however, is uncertain, and the impact of fetal diagnosis of total anomalous pulmonary venous drainage on clinical outcomes is yet to be fully clarified.

Echocardiography is also helpful in monitoring pulmonary veins for obstruction during preoperative and long-term postoperative follow-up. The demonstration of turbulence in the pulmonary veins can be used as a sensitive marker for the presence of obstruction in the pulmonary venous circuit. Because obstruction in the pulmonary veins late after surgical repair can progress in a clinically silent fashion, the sensitivity of the

FIGURE 115-8 ■ Graph showing the distribution between operative survival and the pulmonary veins diameters sum at the confluence indexed to body surface area (BSA). The straight line is the regression line for indexed pulmonary vein sum and BSA derived from normal data. (From Jenkins KJ, Sanders SP, Orav EJ, et al: Individual pulmonary vein size and survival in infants with totally anomalous pulmonary venous connection. *J Am Coll Cardiol* 22:201–206, 1993.)

echocardiogram to detect the presence of turbulence in the pulmonary vein may allow early detection and correction of pulmonary vein stenosis after repair.

Cardiac Catheterization

Cardiac catheterization is used infrequently for diagnosis of routine total or partial anomalous pulmonary venous drainage. Cardiac catheterization is helpful when echocardiographic findings are ambiguous or when the patient has other complex defects. A classic finding at catheterization associated with total anomalous pulmonary venous drainage is identical oxygen saturations in all chambers of the heart. This occurs because of upstream mixing of oxygenated pulmonary venous effluent and deoxygenated systemic venous blood, and subsequent delivery of partially saturated blood to the right side of the heart, as well as to the left side of the heart through the atrial septal defect. Catheterization is also helpful in defining the anatomy of pulmonary vein stenosis, which can develop after repair of total anomalous pulmonary venous drainage.

Catheterization is helpful when the patient needs catheter-based intervention to stabilize the clinical status. Balloon atrial septostomy may be helpful in hemodynamic stabilization before surgical repair in patients with obstruction of pulmonary venous return at the level of a restrictive atrial septal defect. In this situation, the relief of an obstruction at the atrial septal defect allows increased right-to-left shunting and improved systemic cardiac output. Stent placement in the obstructed vertical vein in a patient with infracardiac total anomalous pulmonary venous drainage has been reported (see Fig. 115-7).^{29,32} These procedures may temporarily stabilize critically ill patients with obstructive anomalous pulmonary venous drainage, allowing time to recover from multiorgan dysfunction before definitive surgical repair.

Magnetic Resonance Imaging

Recently, magnetic resonance imaging has emerged as an important diagnostic tool in evaluating total anomalous pulmonary venous drainage. It offers complete visualization of all pulmonary veins, with precise delineation of stenotic segments. In addition, it offers hemodynamic evaluation, including measurement of segmental blood flow and blood flow velocity of the pulmonary veins, calculation of the pulmonary-to-systemic blood flow ratio (Q_p/Q_s) and the possibility of three-dimensional reconstruction.⁷

Computed Tomography Angiography

Computed tomography angiography can be used to define the anatomy of the total anomalous pulmonary venous return because of its superior spatial definition and its shorter examination duration compared with magnetic resonance imaging. Computed tomography also allows the creation of three-dimensional reconstruction of the cardiac structures. The disadvantages are related mainly to exposure to ionizing radiation, more nephrotoxic contrast used and due to the fact that

computed tomography does not provide any hemodynamic measurement. Computed tomography can be used in cases in which magnetic resonance imaging cannot be performed or is contraindicated.³³

Surgical Repair

The goal of surgical intervention is to create unobstructed egress of blood from the pulmonary veins into the left atrium. Aorto-bicaval cannulation offers the flexibility to repair all forms of total anomalous pulmonary venous drainage. In some centers, deep hypothermic circulatory arrest is preferred to allow improved visualization of the pulmonary veins in a bloodless field. Continuous perfusion techniques require the use of cardiotomy suction devices in the pulmonary veins to allow visualization during the repair. For this reason, systemic hypothermia is used to allow the safe decrease of perfusion flow rates during the critical portions of the anastomosis.

After initiation of CPB, ductus arteriosus ligation, and systemic cooling to 18° to 20° C, the aorta is cross-clamped, and cold antegrade blood cardioplegia is administered. The vertical vein is ligated. The pulmonary venous confluence is seen in the posterior pericardium by retracting the heart anteriorly and to the right. Because of the lack of pulmonary vein attachments to the left atrium, the heart is usually mobile, and retraction of the heart out of the mediastinum offers excellent exposure of the pulmonary venous confluence. A longitudinal incision is created in the pulmonary venous confluence to match a corresponding incision in the posterior left atrium, extended out towards the left atrial appendage. With care to avoid distortion, a left-atrial-to-pulmonary-confluence anastomosis is made using fine sutures. Controversy exists regarding the use of absorbable versus nonabsorbable sutures, as well as interrupted versus

continuous techniques.^{34,35} With all techniques, the primary goal is to create a large, unobstructed anastomosis, and the superiority of any one of these techniques has not been convincingly demonstrated. A short period of low-flow CPB may be needed to improve visualization during construction of a meticulous anastomosis.

The use of the approach described in the preceding paragraph is applicable to all types of total anomalous pulmonary venous drainage. It can be challenging, however, to orient the left atrial and pulmonary vein confluence incisions while simultaneously retracting the heart. Furthermore, the retraction required to visualize the anastomosis can place tension on the developing suture line during construction of the anastomosis. Finally, the left atrium tends to be small in patients with total anomalous pulmonary venous drainage and, consequently, the limitation to rightward extension of the anastomosis by the atrial septum can limit the size of the anastomosis. The limitation imposed by the location of the atrial septum is a greater issue in patients in whom the pulmonary venous confluence is oriented rightward with respect to the left atrium.

An alternative approach is to create the anastomosis through a generous atriotomy extended transversely across the right atrium and then across the atrial septum (Fig. 115-9). This approach allows visualization of the posterior wall of the left atrium, which allows the surgeon to place the left atrial incision precisely over the area corresponding to the incision in the pulmonary venous confluence. Furthermore, in patients with a small left atrium and rightward displacement of the pulmonary vein confluence, the approach allows patch augmentation of the left atrium when reconstructing the atrial septum and right atrial incision.

A third operative approach to construction of a pulmonary-vein-to-left-atrial anastomosis is between the

FIGURE 115-9 ■ Repair of total anomalous pulmonary venous drainage under hypothermic cardiopulmonary bypass and cardioplegic cardiac arrest. **A**, A right atrial incision is made from the midportion of the right atrium and extends posteriorly to the pulmonary venous confluence (*dashed line*). The incision is carried leftward across the atrial septum to the secundum atrial septal defect (*dotted line*) and posterior across the back of the left atrial wall in the direction of the left atrial appendage. **B**, Retraction of the atrium to the left exposes the pulmonary venous confluence, which is incised as widely as possible (*dashed line*). **C**, A direct anastomosis is constructed between the divided pulmonary veins and the left atrial wall. If the left atrium is small, or if the pulmonary venous confluence is rightward, the left atrial size can be augmented with a patch along the rightward edge of the anastomosis.

aorta and the superior vena cava. Using this technique, the aorta and the superior vena cava are retracted laterally, exposing the dome of the left atrium and the pulmonary vein confluence. This approach is especially helpful in patients with supracardiac variants of total anomalous pulmonary venous drainage. Further exposure can be obtained easily by dividing the aorta.³⁶

Repair of the intracardiac type of total anomalous pulmonary venous drainage is performed using moderate hypothermia and standard cannulation techniques. If obstruction in the individual pulmonary veins is suggested, deep hypothermic CPB is considered for possible circulatory arrest. A transverse right atriotomy is made, and the atrial septum is exposed. If the pulmonary vein confluence enters the coronary sinus, the atrial septum between the patent foramen ovale and the coronary sinus is incised (Fig. 115-10A). The superior aspect of the coronary sinus is unroofed until the left atrial wall and coronary sinus becomes a common chamber without any separating ridge (see Fig. 115-10B). Care must be taken that the incision and resection are not too close to the mitral valve or to individual pulmonary veins. Any connecting vein between the pulmonary venous confluence and the coronary sinus must be completely incised so that there is no residual circumferential connecting vein. If completely unroofed, the pulmonary vein ostia should be easily visualized through the unroofed coronary sinus. A glutaraldehyde-treated or fresh autologous pericardial patch is used to reconstruct the atrial septum, leaving the pulmonary venous drainage to flow through the unroofed coronary sinus into the left atrium (see Fig. 115-10C). Concern has been expressed that this unroofing technique may have a higher risk of late stenosis in patients who have a short segment of venous confluence interposed between the pulmonary venous confluence and the coronary sinus.²⁶ As an alternative, direct anastomosis of the pulmonary veins to the left atrial wall can be performed.

In patients with infracardiac pulmonary venous connections, the pulmonary venous confluence tends to be oriented more vertically, creating a Y-shaped confluence that drains through a vertical vein to the portal system. Consequently, the incision into the left atrium is more vertical or Y-shaped to maximize the size of the newly created left atrium. Some surgeons leave the vertical vein intact to provide a pressure relief “pop-off” if left atrial pressure is high in the early postoperative period because of small left atrial size or poor ventricular compliance.^{37,38}

Poor hemodynamics in the early postoperative period should raise concerns for potential obstruction at the site of the venous anastomosis and for pulmonary hypertensive crisis. Any suspicion of residual postoperative pulmonary venous obstruction should prompt echocardiographic examination to interrogate the pulmonary venous anastomosis. In patients with preoperative pulmonary venous obstruction, chest radiographic findings of pulmonary vascular obstruction persist for several days despite normal hemodynamics. Therefore, the presence of congestion on a chest radiograph is not sufficient to make the diagnosis of postoperative pulmonary venous obstruction. Pulmonary hypertensive crises are a common

FIGURE 115-10 ■ Repair of intracardiac-type total anomalous pulmonary venous drainage. **A**, The atrial septum between the patent foramen ovale and coronary sinus is incised, and the septal tissue surrounded by the dotted lines is resected. **B**, The superior aspect of the coronary sinus is incised until close to the mitral valve, creating a common chamber including the left atrium and the dilated coronary sinus. The surgeon must identify all four pulmonary vein orifices. **C**, A large defect created by resection of the tissue between the foramen ovale and the coronary sinus is patched with a glutaraldehyde-treated or fresh autologous pericardial patch, redirecting the coronary sinus drainage to the left atrium.

feature in the postoperative management of infants after repair of total anomalous pulmonary venous drainage. In many centers, routine postoperative pulmonary artery or right ventricular pressure monitoring allows early detection and treatment of pulmonary hypertensive crises with deep sedation, controlled ventilation, and inotropic support for right-sided heart failure. Inhaled nitric oxide also can be used for postoperative pulmonary arterial hypertension, although it can create paradoxical pulmonary venous hypertension by rapidly increasing the

left ventricular preload in patients with noncompliant or small left ventricles.³⁹

In patients with a small pulmonary venous confluence and small pulmonary veins, direct anastomosis of the divided edge of the pulmonary veins to the left atrial wall can lead to geometric distortion of the pulmonary vein anastomosis, local trauma from handling the delicate pulmonary vein, and local reaction from suture-related ischemia. In patients with small pulmonary vein confluences, the preferred anastomotic technique at the Hospital for Sick Children in Toronto has evolved into a “sutureless” anastomosis.^{40,41} This technique includes a longitudinal incision in the posterior pericardium and the underlying pulmonary venous confluence. A corresponding incision is made in the overlying portion of the left atrium (Fig. 115-11A). In contrast to direct suture techniques, however, the left atrium is not sutured directly to the divided edge of the pulmonary veins. Instead, the left

atrial edge is sutured to the pericardium circumferentially around the pericardial incision, avoiding direct suturing to the pulmonary veins (see Fig. 115-11B). A “neo-atrium” is thereby created, into which the pulmonary veins bleed in a controlled fashion into the remainder of the left atrium and the left ventricle.

Results

Operative survival for patients with total anomalous pulmonary venous drainage has markedly improved in the most recent decade, with survival rates of more than 90% reported in the current era.^{23,25} Long-term prognosis for patients after repair of total anomalous pulmonary venous drainage is also favorable, with relatively few late deaths.^{23,25} Approximately 10% to 17% of patients have some evidence of late pulmonary vein obstruction; therefore, long-term surveillance is important.⁴² Recent studies raise concerns about neurologic development after repair of total anomalous pulmonary venous drainage—concerns associated with the use of deep hypothermic circulatory arrest and metabolic instability at the early postoperative period.⁴³

SPECIAL CONSIDERATIONS

Total Anomalous Pulmonary Venous Drainage in Heterotaxy

Visceral heterotaxy is characterized by abnormalities of multiple organ systems, including the heart, lungs, liver, spleen, and systemic veins. In the subset of patients with asplenia, or right atrial isomerism, cardiac anomalies include a common atrium, common atrioventricular valves, pulmonary outflow tract obstruction, and hypoplastic left or right ventricles resulting in functional single ventricles. Total anomalous pulmonary venous drainage is present in approximately 90% of patients.⁴⁴

Patients with the common combination of total anomalous pulmonary venous drainage and functional single ventricles typically present within the first month of life for palliation.⁴⁴ The type of palliation required is determined by the presence of uncontrolled pulmonary blood flow (e.g., a functional single ventricle with unrestrictive pulmonary valve) or restricted pulmonary blood flow (e.g., pulmonary stenosis or atresia). Superimposed on the alterations of pulmonary arterial flow is the frequent presence of pulmonary venous obstruction, which may be present in up to 30% of patients.⁴⁴ The presence of obstruction, however, may not be readily apparent until after augmentation of pulmonary blood flow (e.g., systemic-to-pulmonary shunt) in patients initially displaying pulmonary stenosis or atresia.⁴⁵ The majority of these patients have increased muscularity of the pulmonary arteries and “arterialization” of the pulmonary veins.

Patients requiring palliation in the neonatal period often have a complex combination of physiologic problems because pulmonary venous obstruction may coexist with either an unrestricted source of pulmonary blood flow or a restricted source of pulmonary blood flow. Thus, the patient might require repair of obstructed total

FIGURE 115-11 ■ Primary repair of infracardiac total anomalous pulmonary venous drainage using a “sutureless” technique. **A**, The heart is retracted anteriorly and rightward, exposing the pulmonary venous confluence. **B**, The vertical vein is ligated, and the divided edges of the left atrial wall are sutured to the posterior pericardium using a suture line that is remote from the incised pulmonary venous confluence.

anomalous pulmonary venous drainage in combination with pulmonary artery banding or a systemic to pulmonary artery shunt—with a poor prognosis.^{44,45} Recent reports suggest that aggressive repair of total anomalous pulmonary venous drainage repair for right atrial isomerism is associated with improved survival in the more recent era. The sutureless repair is associated with a trend for improved survival but so far has not shown statistical significance for this patient subset.⁴⁶

Pulmonary Vein Stenosis After Repair

Development of stenosis after repair of total anomalous pulmonary venous drainage occurs in 5% to 17.5% of patients after initial repair,^{23,42,47,48} and the patients typically present within the first year after initial repair. The obstruction can occur in one of three general patterns. The simplest form involves a ring of fibrosis limited to the site of the anastomotic suture line. The second form is more complex, involving the distal pulmonary veins in a localized region of intimal proliferation. The most complex form involves diffuse retrograde pulmonary vein stenosis extending far into the distal pulmonary veins. These types of obstruction can occur in a unilateral fashion, progressing to complete occlusion of the pulmonary venous drainage of the involved lung.⁴⁷ Patients with unilateral pulmonary vein stenosis have better survival than patients with bilateral stenosis.^{47,48} Diffuse pulmonary vein stenosis after repair is associated with a high mortality rate.

Pulmonary vein obstruction after repair is associated with pulmonary vascular congestion on chest radiographs. On echocardiogram, the principal diagnostic criterion is the presence of turbulence at the pulmonary venous anastomosis.⁴⁹ Angiography can add information to the echocardiographic findings. Because the echocardiographic window can be limited in postoperative patients, angiography can be helpful in defining the status of the pulmonary veins further upstream in the lung—outside the echocardiographic window. Angiography, however, is an invasive procedure and requires the use of ionizing radiation. Contrast-enhanced magnetic resonance angiography is an extremely useful diagnostic modality for pulmonary vein stenosis.⁷ Contrast-enhanced magnetic resonance angiography provides anatomically detailed analysis of the stenotic pulmonary veins at the site of anastomosis and, importantly, in the lung.⁷ The presence or absence of a distal dilated portion of pulmonary vein is a crucial determination in evaluating a patient with pulmonary vein stenosis after repair. Absence of dilation in the intrapulmonary portion of the pulmonary vein precludes the rationale for surgical attempts to decompress the pulmonary veins.

The presence of turbulence at the site of the anastomosis has been postulated to create a cycle of local injury leading to hyperplasia and increasing turbulence, thereby perpetuating a process of diffuse pulmonary vein stenosis. The progression of pulmonary vein stenosis retrograde (upstream) into the lung parenchyma is associated with a poor prognosis. In an animal model, upstream pulmonary vein stenosis is associated with transforming growth factor β 1 expression and progressive obstruction of the

pulmonary veins through a process consistent with endothelial to mesenchymal transition.⁵⁰ Identification of the mediators of progressive upstream pulmonary venous obstruction can lead to pharmacologic therapies as adjuncts to surgical or stent-based decompression at the left atrial-pulmonary venous junction.

Surgical revision of the pulmonary venous anastomosis, lung transplantation⁵¹ and pulmonary vein stenting⁵² are the most commonly prescribed therapies for pulmonary vein stenosis after repair. Pulmonary vein stenting represents a useful approach on acute relief of stenosis, but it is still associated with high reintervention rate and in stent stenosis.⁵² The diameter of the stent correlates with the risk of re-stenosis, and stent diameters larger than 6 mm are associated with more prolonged patency rates.⁵² Drug-eluting stents and stents delivering local doses of radiation or chemotherapy may offer benefit in the future but have not yet been demonstrated to be efficacious.

Surgical Techniques for Pulmonary Vein Stenosis After Repair of Total Anomalous Pulmonary Venous Return

Some surgeons emphasize the importance of prevention of pulmonary vein stenosis after repair by reducing surgical trauma on the endocardium of the pulmonary vein at the time of the initial repair, thereby minimizing the stimulus for ingrowth of the intimal tissue.⁵³ Nevertheless, approximately 10% to 17% of patients develop pulmonary vein stenosis after repair.

If the obstruction is exclusively at the anastomotic site, the surgical revision can be accomplished by resection of the ingrowth tissue obstructing the anastomotic site or by patch enlargement of the left atrial anastomosis. A polytetrafluoroethylene or pericardial patch is commonly used for enlargement. Other conventional approaches for individual pulmonary vein stenosis include endarterectomy and patch venoplasty. These approaches are associated with a high risk of recurrence ranging from 60% to 90%.^{47,48}

Recent reports have described the use of sutureless techniques to treat pulmonary vein stenosis after repair.⁵³ Cardiopulmonary bypass is established with ascending aortic and bicaval cannulation. Patients are cooled for possible low-flow bypass or circulatory arrest to attain a bloodless field. The heart is retracted cephalad, and the posterior aspect of the left atrium is incised in the region of the previous anastomosis. The stenotic pulmonary vein tissue is incised longitudinally leftward and rightward to the level of the pericardial reflection until non-stenotic segments of pulmonary vein are reached, possibly requiring the incision of veins into secondary or tertiary branches in the pulmonary hilum or parenchyma. Stenotic areas in the mediastinum can be resected circumferentially. The left atrial incision is extended to the left atrial appendage, creating a widely open incision. The left atrial edge is then sutured to the pericardium using 6-0 or 7-0 nonabsorbable polypropylene suture extending around the site of pulmonary vein resection or incision. Midterm outcomes with sutureless techniques have

FIGURE 115-12 ■ CT reconstruction of congenital pulmonary vein stenosis: from a posterior view of the chest the reconstruction shows diffuse stenosis of the left pulmonary veins (LPV; arrow) upper compared to unobstructed right lower pulmonary vein (RPV; arrow). Right upper pulmonary severe stenosis is not visualized in this projection.

been reported to be superior to conventional surgical techniques.^{40,41,47,54}

Congenital (Primary) Pulmonary Vein Stenosis

Congenital pulmonary vein stenosis is the syndrome of primary endoluminal stenosis of one or multiple individual pulmonary veins (Fig. 115-12), which is not associated with previous surgery or catheter intervention. Pathogenesis of this entity has been postulated as being an abnormal incorporation of the common pulmonary vein into the left atrium in the later stage of cardiac development.⁵⁵ This anomaly is frequently associated with other congenital heart malformation, ranging from 30% to 80%.^{56,57} Congenital pulmonary stenosis can be discrete stenosis caused by the intimal shelf or diffuse hypoplasia of the pulmonary veins. Pathologic studies have demonstrated the presence of proliferative myofibroblastic cells in the fibrotic tissue.⁵⁰

Clinical presentation of children with congenital pulmonary vein stenosis depends on the number of pulmonary veins involved and on the severity of stenosis in the individual pulmonary veins. Most patients present in the first months to years of life with respiratory symptoms, including tachypnea, and recurrent respiratory infection. Patients with severe pulmonary venous obstruction have signs of pulmonary hypertension.

Prognosis of progressive congenital pulmonary vein stenosis is extremely poor, and it is strongly related to the number of pulmonary veins involved. Breinholt and colleagues⁵⁸ reported 13 patients with congenital pulmonary vein stenosis; 83% of the patients with three or four pulmonary vein stenosis died, whereas all patients with stenosis limited to one or two pulmonary veins survived. Conventional scar excision techniques appear to be associated with less favorable outcomes than sutureless techniques. Survival rates after sutureless repair for pulmonary vein stenosis, as reported by Viola and colleagues,⁵⁹ were 64%, 47%, and 31% at 1, 5, and 10 years, respectively,

and are directly related to the preoperative severity of the stenosis. Sutureless technique reduces in the postoperative period the grade of stenosis and provides a lower incidence of reoperation in the long term but does not prevent intraparenchymal lung disease progression.

In conclusion, the prognosis for these patients is poor with either technique.^{54,59} Pneumonectomy may be necessary for refractory hemoptysis. Lung transplant can be considered as a viable treatment for patients with recurrent stenosis after primary repair or diffuse disease.⁵¹ Encouraging results with bilateral sequential lung transplantation for this entity have been reported by Bharat and colleagues.⁵¹ Catheter intervention for congenital pulmonary vein stenosis had negligible benefits.⁶⁰ The efficacy of new therapies such as sonotherapy or chemotherapy remains uncertain.

OUTCOMES

Complete Atrioventricular Canal Defect

Partial Atrioventricular Canal Defect

SUMMARY

Atrioventricular (AV) canal defects include a spectrum of lesions in which the common etiology appears to be abnormal development of the endocardial cushions, resulting in a defect in the AV septum and AV valves. This group of lesions forms approximately 3% of all major congenital cardiac defects, and approximately half of the patients have Down syndrome.¹ In children with Down syndrome, AV canal defects are seen in 20% to 25%—a 1000-fold increased risk when compared with the incidence in the general population.²

Although AV canal defects constitute a continuum of related anatomic lesions, it is useful to divide them into two main groups³—partial and complete AV canal defects—on the basis of the extent of the interventricular communication.

Partial AV canal defects consist of a large ostium primum atrial septal defect (ASD) and a cleft between the left superior and inferior bridging leaflets. In most cases, there is no interventricular communication. However, when the cleft extends to the crest of the interventricular septum, a small shunt can occur at this location between the two ventricles. There are generally two distinct AV valve orifices, corresponding to the mitral and tricuspid valves. Leaflet tissue joins the left superior and inferior

leaflets together at the crest of the interventricular septum, eliminating the interventricular communication. In general, partial AV canal defects constitute approximately 5% to 10% of all ASDs.

Complete AV canal defects constitute the other end of the spectrum and are the most common form of AV canal defects. There is generally an ostium primum ASD and a nonrestrictive ventricular septal defect (VSD) in the inlet portion of the interventricular septum. One common AV valve orifice is present, with left and right components. An inlet-septal VSD alone does not fall under the heading of AV canal defects, because the AV septum is intact in these malformations and the AV valves usually form normally. On the other hand, some patients have an inlet-septal VSD and a cleft mitral valve with a restrictive or absent interatrial communication; these should be considered to be in the spectrum of AV canal defects.

In this chapter, we describe the principal anatomic features relevant to the preoperative evaluation and surgical management of defects amenable to a two-ventricle repair, and we briefly discuss the features that may preclude such an approach. Surgical techniques with early and late results are described. Various associated cardiac lesions are discussed, in addition to the management of

recurrent mitral regurgitation. We will not discuss the management of AV canal defects associated with heterotaxy syndrome, because the AV canal defect is not the primary pathophysiologic abnormality, and because the anatomy of the AV valve and leaflet configuration are quite different from those of AV canal defects.

ANATOMY

The anatomic malformation that is common to all forms of AV canal defects is a deficiency in the AV septum caused by incomplete embryonic development of superior and inferior endocardial cushion tissue. The common AV canal is normally present during the early tubular stage of fetal life and constitutes the sole connection between the primitive common atrium and the primitive common ventricle. After cardiac looping, the valves of the heart develop in the embryo from precursor structures, called *endocardial cushions*. These endocardial swellings become populated by valve precursor cells formed by a transformation from endothelial to mesenchymal tissue, and they undergo directed growth and remodeling to form the valvular structures and the membranous septa of the mature heart (Fig. 116-1). Abnormal differentiation and remodeling of the cushion mesenchyme into valvuloseptal tissue is thought to be a mechanism for the development of AV canal defects.⁴ The resultant anatomic defect involves the abnormal development of AV valves and the persistence of interatrial and interventricular communications.⁵

The wide variability in the degree of development of the endocardial cushions explains the variability in size and extent of the septal defects and the degree of involvement of the AV valves. Nevertheless, several anatomic features are shared between all types of AV canal defects. These include the following:

- Shortened dimension of the inlet septum-to-ventricular apex, giving the interventricular septum a “scooped-out” appearance. This deficiency in the inlet septum is typically deeper in complete AV canal defects than in partial AV canal defects.
- Lengthened dimension of the outlet septum-to-ventricular apex, resulting in a goose-neck appearance and anterior displacement of the left ventricular (LV) outflow tract. Although the LV outflow tract appears narrow, true LV outflow tract obstruction (LVOTO) is rare in the absence of accessory chordal attachments of the AV valve leaflets to the outflow tract. In the normal heart, the inlet-septum-to-ventricular-apex length and the outlet-septum-to-ventricular-apex length are equal.
- Absence of the usual wedged position of the aortic valve between the AV valves, caused by maldevelopment of the endocardial cushions. This results in elevation and anterior deviation of the aortic valve.
- Decreased contribution of the left lateral leaflet to AV valve circumference. In the normal situation, the posterior mitral leaflet forms two thirds of the mitral valve circumference. In AV canal defects, the left lateral leaflet, which corresponds to the posterior mitral leaflet in the normal heart, forms only a third or less of the circumference of the AV valve.
- Inferior displacement of the AV node and coronary sinus. The bundle of His is also displaced inferiorly, coursing at the inferior rim of the scooped-out basal portion of the interventricular septum.

In addition to these fundamental concepts, anatomic features of significance to the surgeon include the following:

- Size and extent of the interventricular and interatrial communications
- Valve leaflet morphology, including papillary muscle anatomy, valve regurgitation, and presence of chordal attachments to the septum
- Relative balance of the common AV valve orifice over the two ventricles
- Other major associated cardiac and noncardiac defects

The AV valve in a canal defect has an area of apposition of leaflets that, unlike a normal commissure, is not supported by a papillary muscle. This area of apposition is called a *cleft*, and it is the apposition of the superior and inferior bridging leaflets. This cleft is not a commissure,⁶ as was once thought,⁷⁻⁹ for two reasons. First, a commissure is generally supported by chordae on either side of the defect, whereas a cleft is unsupported, with paucity of chordae at the edges. Second, the chordae that arise from the two adjacent leaflets in a commissure usually attach to a single papillary muscle, which promotes coaptation and prevents regurgitation. The chordae that arise from the left superior and inferior leaflets attach to two different papillary muscles; this increases the distracting force during ventricular systole and predisposes to regurgitation through the cleft. The extent of regurgitation is generally mild to moderate, although severe regurgitation can be present.

In 1966, Rastelli and colleagues¹⁰ described a classification of complete AV canal defect based on the extent

FIGURE 116-1 ■ Schematic of complete atrioventricular (AV) canal defect during morphogenesis, with the AV canal region shown in dark gray. Projections from the superior and inferior endocardial cushions normally differentiate into the AV valves and AV septum. AS, Atrial septum; IC, inferior endocardial cushion; LA, left atrium; LV, left ventricle; SC, superior endocardial cushion; Sept 1, septum primum; VS, ventricular septum. (Modified from Van Praagh R, Litovsky S: Pathology and embryology of common atrioventricular canal. *Prog Pediatr Cardiol* 10:115–127, 1999.)

FIGURE 116-2 ■ The Rastelli classification for complete atrioventricular canal defects. **A**, In the Rastelli type A defect, the superior bridging leaflet is divided into two leaflets at the crest of the interventricular septum, corresponding to the right superior leaflet (RSL) and the left superior leaflet (LSL). **B**, In the Rastelli type B defect, the LSL bridges across the septum and attaches to a papillary muscle in the right ventricle. **C**, In the Rastelli type C defect, there is marked bridging of the superior bridging leaflet (SL), making it free floating and unattached to the underlying interventricular septum. LIL, Left inferior leaflet; LLL, left lateral leaflet; RIL, right inferior leaflet; RLL, right lateral leaflet. (Modified from Jacobs JP, Burke RP, Quintessenza JA, et al: Congenital Heart Surgery Nomenclature and Database Project: atrioventricular canal defect. *Ann Thorac Surg* 69:S36–S43, 2000.)

of bridging of the left superior leaflet (LSL) across the interventricular septum (Fig. 116-2). In complete AV canal defects, the left inferior leaflet (LIL) is not well developed; it is usually short and immobile, with rolled edges. The Rastelli classification does not take into consideration the LIL, which displays greater anatomic variation. No clear morphologic relationship exists between the LSL and the LIL.

The most common Rastelli type, present in approximately 55% of patients, is the Rastelli A defect. There is no bridging of the LSL; instead, its chordae attach to the crest of the interventricular septum. The superior bridging leaflet can be divided into left and right components over the crest of the interventricular septum. The inferior bridging leaflet is rarely divided and is often attached by short, dense chordae to the crest of the interventricular septum.

In the rare Rastelli B defect, the superior bridging leaflet is often partially divided into right and left components, with associated mild to moderate bridging of the LSL. Its chordae attach either to the right of the crest of the interventricular septum or to a prominent papillary muscle in the right ventricle, depending on the extent of bridging. The moderator band is often short. The Rastelli B subtype is often associated with unbalanced AV canal defect.

In the Rastelli C defect, there is extensive bridging of the LSL. Its chordae are free floating and are not attached to the underlying crest of the interventricular septum but rather to the anterolateral papillary muscle of the right ventricle. The Rastelli C type of complete AV canal defect can be seen in association with other complex heart lesions such as tetralogy of Fallot (TOF), transposition of the great arteries (TGA), and double-outlet right ventricle (DORV).

The development of the Rastelli classification facilitated the widespread application of corrective surgery for this defect. Although it is an oversimplification and

represents categorization of a continuum of leaflet abnormalities, it may still have a limited role in the repair of complete AV canal defects using the classic single-patch technique. In that setting, recognition of whether the bridging leaflets are undivided over the crest of the interventricular septum is important because undivided leaflets need to be surgically incised into right and left components to allow placement of a patch to close the interventricular and interatrial communications. Even in those settings, however, the Rastelli classification may have limited applications because neither the extent nor the location of naturally occurring divisions in the bridging leaflets is taken into account. The Rastelli classification is of less importance in the double-patch or modified single-patch techniques that are described later in the chapter.

Lev's¹¹ description of the location of the conduction tissue was another important contribution in the field, because it facilitated the development of surgical techniques that avoided injury to the His bundle and the AV node. The coronary sinus ostium and the AV node are displaced inferiorly in AV canal defects. The AV node lies at the junction of the interatrial septum and the hinge point of the AV valve. This places the AV node between the coronary sinus ostium and the crest of the interventricular septum, in the so-called nodal triangle, which is not at the tip of Koch's triangle. The nodal triangle is bound by the inferior extent of the right AV valve annulus, the coronary sinus orifice, and the inferior edge of the interatrial septum (Fig. 116-3). The bundle of His then passes superiorly and anteriorly from the AV node to the crest of the interventricular septum, reaching it where the crest is fused posteriorly with the AV valve annulus. The bundle then travels along the crest of the interventricular septum, in an inferior-to-superior direction, giving rise to the left bundle branches. Before reaching the midpoint of the interventricular crest, it becomes the right bundle branch and heads toward the moderator band and the muscle of Lancisi.¹² The superior aspect of the interventricular septum is devoid of conduction fibers. The only exception is that, in patients with complete AV canal defects and heterotaxy syndrome, two AV nodes may be found.¹³

The relationship between the common AV valve and the ventricles varies. If the AV valve is situated primarily over one ventricle, associated hypoplasia of the contralateral ventricle frequently occurs, which in extreme cases precludes a two-ventricle repair. Abnormal papillary muscle development, such as two closely spaced papillary muscles or a single papillary muscle, is seen in right ventricle–dominant forms of complete AV canal defect. In left-dominant forms, often the papillary muscles are closely spaced and fused to the septum, giving the appearance of chordal attachments to the septum. In fact, the papillary attachments to the septum can usually be divided to achieve a two-ventricle repair in many of these patients.

Approximately 50% to 75% of patients with complete AV canal have Down syndrome, whereas Down syndrome is rare in patients with partial AV canal defects,¹ occurring in less than 10% of these patients. AV canal defects represent approximately 3% of all major congenital cardiac defects and are seen in approximately 25% to

FIGURE 116-3 ■ The location of the atrioventricular (AV) node and the conduction tissue. **A**, Normal heart. Note the location of the AV node at the tip of the triangle of Koch. **B**, AV canal heart. The AV node is now located in the nodal triangle, not at the tip of the triangle of Koch. The coronary sinus, AV node, and bundle of His are displaced inferiorly compared with the normal heart. RA, Right atrium; RBB, right bundle branch; RV, right ventricle. (Modified from Kertesz NJ: The conduction system and arrhythmias in common atrioventricular canal. *Prog Pediatr Cardiol* 10:153–159, 1999.)

30% of patients with Down syndrome. This represents a 1000-fold higher rate than in the general population.² AV canal defects are the most common congenital heart anomaly in patients with Down syndrome. The presence of Down syndrome is thought to accelerate the development of pulmonary vascular obstructive disease (PVOD), especially in the setting of complete AV canal. An additional 15% to 20% of fetuses with AV canal syndrome have heterotaxy syndrome. AV canal defects are present in almost all patients with asplenia and in a high number of patients with polysplenia. Although an underlying

genetic mechanism has not been identified, some intriguing evidence exists in that regard. First, there is a strong association between AV canal defects and Down syndrome. High levels of endostatin, which is known to regulate endocardial cushion development, have been found in patients with Down syndrome. Second, a weaker association exists with heterotaxy syndrome. Third, familial clustering of AV canal defects has been reported.¹⁴ Fourth, the incidence of recurrent congenital heart disease in offspring of patients with AV canal defects is approximately 10%.¹⁵ In another study, approximately 14% of offspring of mothers with isolated AV canal defects had congenital heart disease, usually either TOF or AV canal defects.¹⁶ This contrasts with the 2% to 4% probability of congenital heart disease in children of parents with other congenital cardiac lesions.

PATHOPHYSIOLOGY

A left-to-right shunt is present in patients with AV canal defects, unless PVOD or coexistent right ventricular (RV) outflow tract obstruction is present. Patient presentation depends on the extent of left-to-right shunting, which in turn depends on pulmonary vascular resistance. The amount of left-to-right shunting increases in the first few weeks of life, paralleling the fall in pulmonary vascular resistance. At this stage, symptoms of congestive heart failure, such as poor weight gain, tachypnea, and sweating, begin to appear.

In partial AV canal defects, where an interventricular communication is absent, the shunt is located only at the atrial level. Patients with partial AV canal defects with little or no regurgitation through the AV valves have a clinical presentation similar to that of patients with secundum ASDs. The degree of shunting depends on the size of the ostium primum ASD defect and the relative diastolic compliance of the two ventricles. RV stroke volume is increased, whereas RV systolic pressure may be normal or only slightly increased. Patients may remain asymptomatic for years. An exception is the presence of significant left AV valve regurgitation in the setting of an ostium primum ASD, which is the case in 10% to 15% of patients. The regurgitation increases left-to-right shunting considerably; a left-ventricle-to-right-atrium shunt may also be present. This results in increased RV and LV stroke volume, cardiomegaly, tachypnea, tachycardia, poor feeding, and failure to thrive, leading to progressive heart failure in infancy. Without treatment, patients with partial AV canal defects and large interatrial communications rarely survive beyond 40 years of age, although older patients have been reported.¹⁷ Atrial arrhythmias are common, increase in frequency with advancing age, and are a poor prognostic sign.

Patients with complete AV canal defects exhibit left-to-right shunting because the VSD is large and nonrestrictive. The extent of the shunt at the ventricular level depends primarily on pulmonary vascular resistance. The pathophysiology in complete AV canal defects is similar to that of a large nonrestrictive VSD with two additional features. First, an atrial level shunt is present, with the potential for a left-ventricle-to-right-atrium shunt and

increased volume loading of the ventricle. Second, AV valve regurgitation may be present, further increasing the volume load. These factors accelerate the development of heart failure symptoms in early infancy.

In many patients, particularly those with Down syndrome, pulmonary vascular resistance remains elevated after birth, which decreases the magnitude of left-to-right shunting. In other infants, pulmonary vascular resistance drops in the first few weeks of life, resulting in a large left-to-right shunt. Patients typically display tachypnea, failure to thrive, cardiomegaly, and diminished distal perfusion in the first few months of life. If AV valve regurgitation is coexistent, the extent of left-to-right shunting is increased because of shunting at both atrial and ventricular levels, resulting in biventricular volume overload. This accelerates the development of heart failure. In one study, moderate AV valve regurgitation was present in approximately 20% of complete AV canal defects, whereas severe regurgitation was present in 15% of such lesions.¹⁸ In our experience,¹⁹ mild AV valve regurgitation is common, occurring in approximately 35% of patients in the first year of life, although the incidence of severe AV valve regurgitation is less frequent, occurring in approximately 4% of patients.

Irreversible changes in the pulmonary vasculature are seen as early as 6 months in patients with unrepaired complete AV canal defects.²⁰ The presence of Down syndrome accelerates the development of PVOD.²¹ This can result partly from an underlying pulmonary vascular defect predisposing to PVOD and partly from increased bronchial secretions, decreased number of distal bronchi, inherent abnormalities of the lung parenchyma, and the thick tongue that predisposes to oropharyngeal airway obstruction, hypoventilation, sleep apnea, tracheobronchomalacia, and CO₂ retention. These factors accelerate the development of respiratory infections and PVOD. If PVOD progresses, eventually the shunt reverses to a right-to-left shunt and the Eisenmenger complex develops, with progressive cyanosis in later stages.

Without surgery, patients with complete AV canal defects and Down syndrome have an 80% survival rate at 10 and 15 years.²² The primary causes of death within the first several years of life are heart failure and recurrent pulmonary infections. Subsequently, PVOD becomes an increasingly prevalent cause of death. Toward the end of the second decade of life, exercise tolerance begins to decrease progressively, leading to premature death from PVOD by the third to fourth decades of life. One of the more dramatic causes of death in patients with PVOD is massive hemoptysis, which can occur as early as the third decade of life.

TIMING OF SURGERY

The development of surgical techniques to treat AV canal defects parallels the evolution of cardiac surgery for congenital heart defects. Initial attempts at repair were complicated by limited knowledge of the anatomic features, particularly regarding the conduction tissue.

The first cardiac operation using a pump oxygenator was attempted by Dennis and Varco in 1952 in a patient

with a preoperative diagnosis of an ASD. The patient did not survive surgery. Postmortem examination revealed a partial AV canal defect. In 1955, Lillehei and colleagues²³ were the first to report repair of complete AV canal using cross-circulation. Successful repair of an ostium primum defect using cardiopulmonary bypass was first reported by Kirklin and colleagues in 1955.²⁴

Complete Atrioventricular Canal

Two techniques have been proposed for repair of complete AV canal defects. A single patch covering atrial and ventricular defects with partition of the superior bridging leaflet was originally developed by Rastelli and Kirklin at the Mayo Clinic.^{25,26} Separate atrial and ventricular patches were proposed by Carpenter⁸ and advocated by others.^{27,28} A recent modification of the single-patch technique has been introduced.^{29,30}

Management of the cleft has evolved over the years. Carpentier,⁸ Anderson and associates,⁷ and others⁹ recommended that the cleft be viewed as a commissure. They advocated leaving the cleft open to result in a "trifoliate" left AV valve and prevent the development of stenosis. However, the left-sided cleft is not a normal commissure, as discussed earlier. Left AV valve regurgitation frequently originates at the cleft; in later stages, as the regurgitation progresses, a central regurgitant jet may also be seen. Many surgeons in the 1980s left the cleft open only to have a sizable number of patients return with significant mitral regurgitation (MR) primarily through the cleft. For this reason, most surgeons close the cleft completely. However, the cleft should be left open or only partially closed in patients with a single papillary muscle in the left ventricle, the so-called parachute mitral valve, because mitral stenosis can result when complete cleft closure is undertaken in this setting.

Many surgeons during the 1970s and early 1980s advocated palliation with pulmonary artery banding to delay surgical repair beyond infancy. However, as surgical techniques improved and cardiopulmonary bypass in infants became safer and more widely applied, most centers abandoned this practice and opted for elective repair before 6 months of age. One exception is children with partial and transitional AV canal defects, who are frequently asymptomatic; repair can generally be deferred until the first few years of life unless AV valve regurgitation is severe. Although we advocate primary repair of complete AV canal in early infancy, there may be a limited role for the use of a palliative pulmonary artery band in patients with highly complex anatomy, such as unbalanced complete AV canal defects in which single-ventricle management is planned. Palliation by construction of a modified Blalock-Taussig shunt has been proposed in patients with complete AV canal defects and TOF to avoid early repair; although we do not advocate this approach, it will be discussed later.

We advocate repair in symptomatic infants regardless of age, and elective repair within the first 2 to 4 months of age in asymptomatic infants with complete AV canal defects. Delay beyond this age is unnecessary and is potentially hazardous. Repair of AV canal defects beyond 6 months of age has recently been shown to be

an incremental risk factor for death.³¹ Freedom from reoperation for left AV valve regurgitation is higher when patients are repaired at a younger age.³¹ Prematurity and severe AV valve regurgitation should not be contraindications for corrective surgery, because the results with palliation in these groups are particularly poor.

Another sequela of delaying surgery is the development of pulmonary hypertension with elevated pulmonary vascular resistance, predisposing to postoperative pulmonary hypertensive crises, which are serious and life-threatening postoperative complications. Although pulmonary hypertension can, in most cases, be treated with sedation, hyperventilation, and inhaled nitric oxide, prevention by timely elective repair is far safer and avoids the risk of development of irreversible PVOD, which can occur within the first year of life, especially in the presence of Down syndrome.

Transitional Atrioventricular Canal

Patients with transitional AV canal defects fall in a category between partial and complete AV canal because of the restrictive nature of the VSD, which protects against the harmful sequelae of torrential pulmonary blood flow. Usually, the restrictive VSD is small, which allows transitional AV canal defects to be repaired in the first 1 to 2 years of life. If the restrictive VSD is moderate in size, then repair should proceed earlier to prevent the complications of PVOD.

Partial Atrioventricular Canal or Ostium Primum Defects

Asymptomatic patients with partial AV canal defects should be repaired by 1 to 3 years of age in the majority of patients. This is similar to the recommendation for closure of isolated secundum ASDs. If significant left AV valve regurgitation is present, then earlier repair is recommended.

Sommerville³² reviewed the outcome of 122 unoperated patients with ostium primum ASDs between 1958 and 1964. Increasing morbidity and mortality occurred with increasing age. The presence of significant MR correlated with increasing symptoms. Of 96 patients younger than 30 years of age, 14% died ($n = 5$) or had significant disabling symptoms ($n = 8$).

A subgroup of patients with partial AV canal defects display heart failure symptoms that are unresponsive to medical management in the first year of life.³³ They require early surgical correction. Frequent associated findings include the presence of several left-sided obstructive lesions such as hypoplasia of the left AV valve, the left ventricle, the aortic valve, and the aortic arch, in addition to aortic coarctation. Complex mitral valve anomalies have also been documented in this subset of patients.³⁴

PREOPERATIVE EVALUATION

Because of the nearly continuous spectrum of lesions involving the atrial, ventricular, and valvular portions of

the AV canal defects, preoperative definition of the anatomic features in each case is helpful. Information regarding the mechanism of valve regurgitation and LVOTO are especially valuable in planning operative intervention. Intraoperative confirmation of the anatomic features is imperative to guide decisions regarding patch size, position of valve leaflets, and extent of cleft closure.

Physical examination correlates with the type of AV canal defect. In patients with partial AV canal defects, a systolic pulmonary flow murmur is heard, along with fixed wide splitting of the second heart sound, as in a secundum ASD. An apical blowing systolic murmur of MR may be present. If a VSD is present, as in transitional or complete AV canal defects, then a harsh holosystolic murmur is present, best heard at the left lower sternal border or the ventricular apex. A hyperactive precordium may be present. P2 is often loud, with fixed splitting of the second heart sound. Often a mid-diastolic low-pitched rumble is present. A pulmonary flow murmur may also be present.

The electrocardiogram reveals marked RV hypertrophy and sometimes may reveal LV hypertrophy and biatrial enlargement. The PR interval is often prolonged. The chest radiograph shows evidence of increased pulmonary blood flow, along with cardiomegaly. The presence of left AV valve regurgitation accentuates these findings; the left atrium may be severely dilated, with resultant elevation of the left main-stem bronchus.

In nearly all cases, the anatomic features, associated defects, and mechanism of valve dysfunction can be obtained from two-dimensional echocardiography, along with Doppler evaluation of blood flow direction and velocity.³⁵ The four-chamber view shows the left and right AV valves at the same horizontal level, which is in contradistinction to the normal situation, in which the tricuspid valve is attached to the AV septum more toward the apex of the heart than the mitral valve. Other features on echocardiography include the elongated LV outflow tract and the unwedged aortic valve. It is important to assess the presence of chordal attachments to the LV outflow tract, because this is a substrate for the development of LVOTO. The AV valve leaflets should be examined, and the mechanism of AV valve regurgitation should be assessed carefully. The availability of real-time three-dimensional echocardiography (RT-3DE) has been helpful in the assessment of the defect and to determine the mechanism of regurgitation. We use either epicardial or transesophageal RT-3DE in the assessment and management of AV valve repair, especially in reoperations for AV valve regurgitation. Studies have shown that RT-3DE can be used successfully in the repair of AV canal defects, with a short learning curve.³⁶ Echocardiography can be used to determine whether the common AV valve is balanced or not.³⁷ Using a subcostal view and planimetry technique, the area of the AV valve positioned over the left ventricle is divided with the area of the AV valve positioned over the right ventricle to derive the AV valve index. The valve index can be used to determine how balanced or unbalanced the AV valve complex is and to guide the treatment process.

For the majority of patients, cardiac catheterization and angiography rarely add information not obtained by

echocardiography. One notable exception is the unoperated patient older than 1 year in whom measurement of pulmonary vascular resistance is needed to determine operative risk. Another exception is the postoperative patient in whom quantification of residual postoperative lesions, such as residual VSDs and LVOTO, are required to assess the need for reoperation.

SURGICAL TECHNIQUE

Median sternotomy, either partial or complete, has been the standard technique for exposing the heart and great vessels. Some have advocated a right anterior thoracotomy for partial AV canal defects in older female children to improve cosmesis. More recently, however, techniques to minimize surgical trauma by limiting the extent of the sternotomy have been used, such as a lower mini-sternotomy (Fig. 116-4).³⁸ This approach can be applied to infants and children of all ages and may be helpful in decreasing postoperative pain and development of chest wall deformities, such as pectus carinatum. We are now using this mini-sternotomy approach for nearly all AV canal defects, except when there are major associated cardiac lesions such as aortic coarctation, TOF, or TGA, where a full sternotomy is required for optimal exposure.

Cardiopulmonary bypass with moderate hypothermia and bicaval cannulation is used in nearly all cases; deep hypothermic circulatory arrest is rarely required. Aortic cross-clamping and cardioplegia are used in all cases to facilitate repair, particularly during the attachment of the septal patches near the AV node and coronary sinus.

In the setting of a large ostium primum ASD, both AV valves and intraventricular anatomy can be readily visualized. If a small or absent interatrial communication is present, then an incision in the septum primum provides access to the left AV valve for valve testing and cleft closure. This also aids in securing the VSD patch to the crest of the interventricular septum.

Complete Atrioventricular Canal

In complete AV canal defects, there is usually a large ostium primum defect and a moderate to large nonrestrictive VSD under the superior and inferior bridging leaflets (Fig. 116-5). There may be chordal attachments of either bridging leaflet, or both, to the crest of the septum, and these leaflets may be partitioned into right and left components or may form a single bridging leaflet over the crest of the septum. Two surgical approaches have been developed and are commonly used in this setting. A double-patch technique involves the placement of two separate patches, one to close the VSD and the other to close the ASD. Alternatively, a single-patch technique with autologous pericardium is used to close the VSD and ASD components, often with division of the superior bridging leaflet. More recently, a modified single-patch technique has been introduced, where the VSD is obliterated by suturing the bridging leaflets to the crest of the interventricular septum; a single pericardial patch is then used to close the ASD. Although there are

advantages and disadvantages to each technique, excellent results have been reported with all three methods.

Double-Patch Technique

In the double-patch technique, separate patches are used for closure of the ventricular and atrial septal defects. The ventricular patch is made of synthetic material, such as Dacron, or glutaraldehyde-treated pericardium. The atrial patch is usually autologous pericardium, either untreated or treated with glutaraldehyde. The use of a

FIGURE 116-5 ■ Surgeon's view of complete atrioventricular (AV) canal defect. The superior bridging leaflet (*left*) is undivided and unattached to the underlying crest of the interventricular septum, as in a Rastelli type C defect. The AV node and coronary sinus ostium are displaced inferiorly. There is a cleft between the left superior and inferior leaflets. A large ostium primum defect is present, allowing good visualization into the left atrium.

synthetic atrial patch should be avoided, because hemolysis can result when a left AV valve regurgitant jet strikes the patch.

Initial inspection of the AV valve and filling of the left ventricle with cold saline facilitates the delineation of the point of coaptation of the left superior and inferior bridging leaflets. This permits measurement of the base-to-apex dimension of the VSD at the point of leaflet coaptation, corresponding to the height of the VSD patch. The distance between the two junction points of the interventricular septum and the AV valve annulus, at the aortic valve cephalad and the AV node caudad, should also be determined. This is helpful in determining the width of the VSD patch.

The patch shape is that of a crescent rather than a half circle because of the apical displacement of the point of coaptation of the superior and inferior bridging leaflets (*Fig. 116-6A*). The VSD patch is attached to the right of the crest of the interventricular septum using running or horizontal mattress interrupted pledgeted sutures. Care should be taken to avoid distortion of valve chordae that attach to the septum. As the suture line approaches the AV node area, the patch is attached more to the right of the septum, fixed 3 to 4 mm away from the junction of the interventricular septum and the AV valve.

The superior and inferior leaflets are then draped over the edge of the VSD patch. The pericardial patch is cut to an appropriate width, made narrower than the true distance between the aortic valve and the AV node to perform an annuloplasty of the AV valve, thereby decreasing the incidence of MR. A running horizontal suture line is performed to sandwich the AV valve leaflets between the VSD and ASD patches. These sutures pass through the pericardial patch, the left AV valve leaflets, the VSD

FIGURE 116-6 ■ The double-patch technique for repair of complete atrioventricular (AV) canal defects. **A**, Placement of the crescent-shaped ventricular septal defect (VSD) patch, showing suturing to the crest of the interventricular septum. The superior leaflet is retracted cephalad to allow accurate suturing without entrapment of chordae. Similar retraction is used at the inferior leaflet, where the patch is sewn to the right of the crest of the interventricular septum to avoid iatrogenic injury to the AV node. **B**, Completion of the double-patch repair is achieved by inserting the atrial septal defect (ASD) patch. Sutures are passed through the VSD patch, valve leaflets, and ASD patch, thereby sandwiching the valve between the two patches. In this example, the ASD patch is sewn to the right of the AV node and to the left of the coronary sinus. If a secundum defect or patent foramen is present, the ASD patch can be extended to cover both defects. Cleft closure is usually completed once the valve leaflets are attached to the ASD and VSD patches. *Inset*, Apposition of the cleft edges during systole.

FIGURE 116-7 ■ Closure of the left atrioventricular (AV) valve cleft. Once the leaflets are attached to the ventricular septal defect and atrial septal defect patches, the zone of apposition of the superior and inferior bridging leaflets is usually well aligned. The cleft is then closed in two layers. **A**, The first layer is a running mattress suture, apposing the edges of the leaflets. **B**, The second running simple suture line ensures apposition of the leaflet edges. **C**, When there is significant annular dilation, a posterior annuloplasty is performed by inserting a flexible partial ring from the anterior fibrous continuity with the aortic valve to just posterior to the interatrial septum. The latter should remain 3 to 4 mm posterior to the junction between atrial septum and AV valve annulus to avoid injury to conduction tissue.

Dacron patch, and the right AV valve leaflets (see Fig. 116-6B).

The mitral valve cleft, created by coaptation of the superior and inferior bridging leaflets, is then closed, using either running or interrupted horizontal mattress sutures (Fig. 116-7A, B). Our preferred technique is the double-layer cleft closure. The first layer is a horizontal mattress layer, and the second layer is a simple running over-and-over suture, which is not tightened but left loose enough to help the pliability of the unified leaflet. The extent of cleft closure is determined in great part by the position of the papillary muscles and the size of the left lateral leaflet. Because closure of the cleft limits mobility of the superior and inferior leaflets, the greater the valve orifice area that is covered by these two leaflets, the greater the chance for creating valve stenosis. When the papillary muscles are close together or a single papillary muscle is present, closure of the cleft creates a slit-like orifice of the mitral valve, resulting in significant stenosis. In these cases, the cleft must be left at least partially open to facilitate leaflet mobility. Frequently, the edges of the leaflets creating the cleft are rolled and coapt over a small surface area. Care must be taken to preserve this degree of coaptation in closing the cleft and not to unroll the leaflet edges, because leaflet coaptation adds strength to the cleft closure, particularly during systole, thereby minimizing MR (see Fig. 116-6B).

The degree of MR is determined by injecting cold normal saline into the LV cavity. If significant regurgitation is present after cleft closure, then central regurgitation from poor leaflet coaptation is the usual culprit. This is managed by narrowing the commissure between the LSL and the left lateral leaflet and the LIL and lateral leaflet with placcation sutures. When there is annular dilation, placing a posterior intra-annular absorbable suture from LIL to LSL suspends the entire lateral leaflet. This brings the left lateral leaflet closer to the interventricular septum and improves central leaflet coaptation. An

additional maneuver that we have used when the left lateral leaflet does not coapt well with the sutured anterior leaflet is a posterior suture annuloplasty. We perform this maneuver using an absorbable monofilament suture, placing the suture in the annulus and then tying the suture over an appropriate sound to avoid valve stenosis. Commercially available posterior annuloplasty bands made of absorbable material can also be useful in cases of recurrent AV valve regurgitation (see Fig. 116-7C).

The ASD patch is then sutured to the remnants of the interatrial septum. The two surgical options available for avoiding injury to the AV node are attachment of the patch to the right or to the left of the AV node. Attaching the ASD patch to the right of the AV node involves suturing to the *right* inferior leaflet, where superficial bites are taken. The suturing continues to the right of the coronary sinus orifice, leaving the coronary sinus draining into the left atrium (Fig. 116-8A). Alternatively, the suturing can be extended to the edge of the coronary sinus orifice, leaving the orifice on the right atrial side (see Fig. 116-8B). The advantage of placing the patch to the right of the coronary sinus ostium is that the suture line remains far from conduction tissue. The disadvantage is that the coronary sinus is left draining to the left atrium. This can cause variable degrees of obstruction to coronary sinus drainage unless the coronary sinus is surgically unroofed. The arterial saturation is typically minimally affected. In a variant of this latter technique, the ASD patch can be attached to the *left* inferior leaflet, gradually returning to the edge of the interatrial septum, as initially advocated by McGoon and colleagues.²⁵ This leaves the coronary sinus draining into the right atrium. The disadvantage of this technique is that sutures must be placed through the LIL; in small infants, these sutures can tear through the delicate leaflet tissue or distort the leaflet enough to cause significant MR. In patients with complete AV canal and a left superior vena cava draining to the coronary sinus, the patch should be to the right of

FIGURE 116-8 ■ Placement of the atrial septal defect (ASD) patch. **A**, The ASD patch can be placed entirely to the right of the atrioventricular (AV) node and coronary sinus, leaving the coronary sinus on the left atrial side of the newly constructed septum. **B**, Alternatively, the patch can be placed to the right of the AV node, but by turning the suture line back to the left of the coronary sinus, the sinus is left on the right atrial side.

the AV node and sutured to the edge of the coronary sinus ostium, leaving the ostium draining into the right atrium (see Fig. 116-8B).

Classic Single-Patch Technique

In the classic single-patch technique, the same patch of autologous pericardium, usually treated with glutaraldehyde, is used to cover both ventricular and atrial septal defects (Fig. 116-9).³⁹ It is critically important to determine the position of the mitral cleft and superior bridging leaflet with respect to the crest of the interventricular septum. When the right and left components of the AV valve are already partitioned with chordal attachments to the crest of the septum, only the position of the mitral valve cleft needs to be determined. Often, incisions must be made in the superior and inferior bridging leaflets parallel to and to the right of the interventricular septum to permit proper positioning of the single patch. The extent of leaflet division depends on the extent of the

underlying VSD. Because the VSD under the superior bridging leaflet often extends to the AV valve annulus, the leaflet incision has to extend to the AV annulus as well. This is often not the case for the inferior bridging leaflet, especially in the Rastelli A subtype, where the underlying VSD may not extend to the AV valve annulus because of variable fibrous fusion between the LIL and the crest of the interventricular septum. The leaflet incision in that case is only partial, without extension to the AV valve annulus. This protects the conduction tissue and AV node from iatrogenic injury. When the VSD under the inferior bridging leaflet extends to the AV valve annulus, the division of the leaflet should be to the right of the crest of the interventricular septum. This allows placement of the patch toward the right, thereby avoiding injury to the underlying conduction tissue at the crest of the interventricular septum.

As with the double-patch technique, precise measurement of the width of the patch with respect to the width of the AV canal defect is necessary to prevent MR caused by distortion of valve leaflets. If the patch is too wide, then the AV valve annulus size will increase, particularly over the interventricular septum; the superior and inferior bridging leaflet tissue available might not be sufficient to cover the orifice, resulting in MR.

Once the AV valve is partitioned into the right and left components, the VSD patch is attached to the right of the crest of the interventricular septum using running or interrupted pledgeted sutures. As with the double-patch technique, the suture line is placed to the right of the crest of the interventricular septum to avoid injury to the bundle of His. Once the patch is attached to the ventricular septum, the AV valve leaflets must be reattached to the patch. This maneuver is greatly facilitated by prior placement of a suture marking the coaptation point of the LSL and LIL at the base of the cleft at the crest of the interventricular septum. The valve leaflets should not be reattached too far to the atrial side of the patch, because this would tether the leaflets and limit coaptation, resulting in MR. Attachment of valve leaflets to the patch is done with pledgeted sutures because these valve leaflets are thin and friable, particularly in infants, predisposing to tearing if attached with nonpledgeted sutures.

The mitral cleft is closed next. The same considerations regarding cleft closure as described for the double-patch technique are applicable here. Similarly, individual commissuroplasty sutures can be placed for the treatment of central left AV valve regurgitation. The patch is then sutured to close the interatrial communication. As discussed earlier for double-patch repair, the coronary sinus may be left draining into the right or left atrium.

Modified Single-Patch Technique

The original description of complete AV canal repair by Dr. Lillehei involved attaching the AV valve leaflets to the crest of the interventricular septum primarily, because patch material was not readily available at the time; the ASD was also closed primarily.²³ Wilcox and colleagues³⁰ reintroduced this method of repair for patients with small VSDs. Nicholson and colleagues²⁹ broadened

FIGURE 116-9 ■ Classic single-patch technique for repair of complete atrioventricular (AV) canal defects. **A**, Alignment sutures placed through the left superior leaflet and left inferior leaflet at the crest of the interventricular septum. **B**, The superior bridging leaflet is incised. **C**, Two portions of the superior bridging leaflet (*a* and *c*) and two portions of the inferior bridging leaflet (*b* and *d*) are shown after division of the corresponding leaflets. The division of the inferior bridging leaflet need not extend beyond the underlying interventricular communication. **D**, The left-sided cleft is closed. **E**, The pericardial patch is sewn to the crest of the interventricular septum. **F**, The right and left AV valve leaflets are suspended onto the pericardial patch. **G**, Completion of the repair by closure of the atrial septal defect. The AV node and coronary sinus ostium are shown draining on the left atrial side. (Modified from Castaneda AR, Jonas RA, Meyer JE Jr, et al: Atrioventricular canal defect. In Castaneda AR, Jonas RA, Meyer JE Jr, et al, editors: *Cardiac surgery of the neonate and infant*, Philadelphia, 1994, WB Saunders, p 179.)

the indications to patients with moderate and large VSDs. Other reports have confirmed their findings.^{40,41}

In this technique, several pledgeted horizontal mattress sutures are brought through the crest of the interventricular septum, the AV valve leaflets, the autologous pericardial patch, and a narrow strip of Dacron, in that order (Fig. 116-10). Care should be taken to avoid damage to the bundle of His by keeping the sutures to the right of the crest of the interventricular septum, especially inferiorly. Suturing through the AV valve leaflets effectively partitions the bridging superior and inferior leaflets into right and left components. The strip of Dacron acts as an annuloplasty because its superior-inferior dimension is approximately 80% of the superior-inferior dimension of the AV canal defect, thereby bringing the left-sided AV valve leaflets into closer apposition and minimizing MR. Some have advocated avoiding the use of a strip of Dacron because of concerns about the effect of fixation of the mitral annulus on its long-term growth potential. One potential disadvantage of this technique is the development of LVOTO because the interventricular communication is closed primarily, without patch material. So far, although follow-up is limited, this has not been seen. The amount of MR appears similar to that seen with the classic single-patch and double-patch methods, although long-term follow-up is not yet available.

FIGURE 116-10 ■ Modified single-patch technique for repair of complete atrioventricular (AV) canal defects. Horizontal mattress pledgeted sutures are passed through the crest of the interventricular septum, the AV valve leaflets, and the pericardial patch, and then through a Dacron strip annuloplasty. (Modified from Nicholson IA, Nunn GR, Sholler GF, et al: Simplified single patch technique for the repair of atrioventricular septal defect. *J Thorac Cardiovasc Surg* 118:642–646, 1999.)

Transitional Atrioventricular Canal

In this form of AV canal defect, the VSD is restrictive and usually centrally located, formed by incomplete fusion of the point of coaptation between the LSL and LIL over the crest of the septum. There is usually a large ostium primum defect and a cleft mitral valve. The bridging leaflets are fused to the crest of the septum except for the central portion, and small VSDs may be found under the superior or inferior leaflets when the leaflets have not completely fused to the crest of the interventricular septum. When the VSDs are small, they can be difficult to identify intraoperatively. Retraction of the right superior leaflet can provide adequate access to these small defects, and a small (1- to 2-mm) probe can be used to identify residual interventricular communications.

These small VSDs can usually be closed primarily with sutures. Closure of the central VSD is usually done with the same suture that is used to close the cleft, but starting at the crest of the interventricular septum. Closure of the interatrial communication is done in a manner similar to ostium primum defects (Fig. 116-11).

Partial Atrioventricular Canal or Ostium Primum Defects

As with repair of complete AV canal, initial inspection and testing of the mitral valve is done. The presence of a partial or complete cleft is noted; in the majority of cases, the cleft extends to the interventricular septum. The technique for cleft closure is the same as that described earlier, with emphasis on maintaining leaflet coaptation. The ostium primum ASD is closed using autologous pericardium, because this tissue is more pliable than synthetic material and is less likely to distort valve leaflets. A secundum ASD or patent foramen ovale, if present, is closed either separately or with the same patch (see Fig. 116-11).

ASSOCIATED CARDIAC LESIONS

Associated cardiovascular lesions are not uncommon, particularly with complete AV canal defects. Extracardiac defects such as patent ductus arteriosus and aortic coarctation are usually treated during the operative procedure for repair of the AV canal defect. The surgical techniques for repair of associated defects are usually not different in the presence of an AV canal defect from when the lesions are isolated defects. Exceptions to this include the presence of secundum ASDs or additional muscular VSDs that are close to the AV canal defect; these can be repaired by extension of the septal patch to cover both lesions. Lesions that include conotruncal abnormalities such as TOF require significant modifications to the surgical approach and are discussed separately.

Tetralogy of Fallot

Tetralogy of Fallot is a complication in approximately 5% of patients with complete AV canal defects. The LSL is typically free floating over the interventricular crest of

FIGURE 116-11 ■ Repair of transitional atrioventricular (AV) canal defect. **A**, The bridging leaflets are usually attached to the crest of the septum (*dashed line*) except for the central area of coaptation where there is a small ventricular septal defect (VSD). **B**, Closure of the VSD is accomplished using the same suture line as was used for cleft closure. Closure of the mitral cleft in this case is done first, then pericardial patch closure of the ostium primum defect is done. The patch is sutured to the right inferior leaflet tissue and then heads down toward the coronary sinus. An alternative technique (not shown) is suturing to the left inferior leaflet tissue, at the rim of the ostium primum defect.

the septum, as in a Rastelli type C defect, resulting in a large VSD with outlet extension. In contrast to the heart failure symptoms seen in the majority of patients with isolated complete AV canal defects, the main symptom in the combined lesion is cyanosis. This occurs because of right-to-left intracardiac shunting, which depends primarily on the degree of RV outflow tract obstruction. In a minority of patients, the degree of RV outflow tract obstruction is minimal; these patients display heart failure symptoms in early infancy that are similar to the symptoms in patients with isolated complete AV canal defects.

The operative management of complete AV canal defects associated with TOF requires modification of the VSD patch, because it has to extend to cover the conoventricular, anteriorly malaligned VSD. As with most forms of TOF, there is frequently infundibular

obstruction, along with pulmonary valvar hypoplasia and stenosis requiring augmentation of the entire RV outflow tract. Because of the anterior position of the aortic valve annulus in this defect, visualization of the anterosuperior edge of the VSD is best accomplished through a right infundibulotomy. As with cases of uncomplicated AV canal defects, the width of the VSD patch at the AV valve annulus level must be chosen carefully to prevent enlarging the AV valve annulus and resulting in MR.

When the single-patch technique is used to repair complete AV canal in association with TOF, an incision in the superior bridging leaflet is usually needed and is particularly critical. This incision should be farther toward the right of the crest of the interventricular septum, toward the right AV valve, to accommodate the underlying anterior deviation of the conal septum. This prevents the development of subaortic obstruction and LVOTO, seen when the patch is placed too far to the left of the interventricular septum. This is less an issue with the double-patch method of repair, although correct positioning of the VSD patch under the superior leaflet is still required. The shape of the VSD patch for the combined lesion resembles a teardrop rather than the typical crescent shape in isolated complete AV canal defect. The modified single-patch technique as originally described is not applicable to canal defects with TOF, because the large malalignment defect precludes direct suturing of the LSL to the crest of the interventricular septum.

Repair of the RV outflow tract obstruction is managed in a manner similar to that of isolated TOF, often with an incision in the RV outflow tract. The major difference in the combined lesion is that MR can result in left atrial hypertension with subsequent pulmonary arterial hypertension. If a transannular patch is used, the regurgitant fraction across the enlarged RV outflow tract is increased, leading to RV distention and dysfunction. The right ventriculotomy combined with division of RV muscle bundles in the outflow tract further exacerbates RV dysfunction. In such cases, consideration should be given to the creation of a temporary single-leaflet valve made from autologous pericardium. Careful testing of the tricuspid valve should be undertaken to rule out the presence of significant tricuspid regurgitation. If present, this can often be repaired by closure of the cleft between the right superior and inferior leaflets while avoiding the underlying conduction tissue.

Some have advocated the placement of a systemic-to-pulmonary shunt (e.g., a right modified Blalock-Taussig shunt) in the neonatal period in patients with severe cyanosis, with subsequent repair at 1 to 3 years of age, which potentially decreases the need for a transannular patch.⁴² We have usually undertaken complete repair in infants to avoid the episodes of hypercyanosis seen in tetralogy physiology. As with management of tetralogy, a small atrial septal communication is left to permit some right-to-left shunting because of RV diastolic dysfunction early after surgery.

Double-Outlet Right Ventricle

An anatomic scenario that can be similar to TOF is DORV, which is differentiated from TOF by the degree

of aortic override. When more than 50% of the aortic valve is located over the right ventricle, the lesion is defined as DORV rather than TOF. DORV is present in approximately 1% to 2% of patients with complete AV canal defects.⁴³ Typically, DORV in this setting is associated with heterotaxy syndrome and unbalanced AV canal defects, increasing the likelihood of univentricular palliation.

Two-ventricle repair of DORV and complete AV canal defects parallels the repair of the two separate lesions. If the VSD is in the subaortic position, the repair is similar to TOF with complete AV canal defect. The patch is more complex, because the left ventricle has to be baffled through the VSD to the aortic valve.

Coarctation of the Aorta

If aortic coarctation is present, the left-sided cardiac structures need to be studied carefully to ensure that they are of adequate size and to rule out unbalanced AV canal with RV dominance. Aortic coarctation has been associated with a mild degree of LV outflow obstruction for valvar or subvalvar stenosis. Often, these patients have closely spaced papillary muscles in the left ventricle or, in extreme cases, a parachute mitral valve with a single papillary muscle.

If significant MR is present after repair of complete AV canal defects, an exhaustive search should be performed to rule out the presence of residual LVOTO or aortic coarctation. If present, this increases LV afterload, which increases the distracting pressure on the thin and friable mitral leaflets and worsens the degree of MR. Repair of aortic coarctation in this setting often decreases the degree of MR.

Left Ventricular Outflow Tract Obstruction

Hemodynamically significant LVOTO is relatively rare in the setting of AV canal defects. Interestingly, LVOTO is rare in the presence of Down syndrome.⁴⁴ It is more common in partial AV canal defects than in complete AV canal defects,⁴⁵ unless ventricular imbalance is present. This may be due to the modification of the LV outflow tract in complete AV canal repair through the insertion of a VSD patch, whereas no such patch is needed during partial AV canal repair because no VSD is present. LVOTO results in an increased left-to-right shunt with accelerated development of heart failure symptoms. LVOTO appears to be more commonly associated with the Rastelli A subtype of complete AV canal.⁴⁶ The development of LVOTO can be acquired, progressive, or recurrent.⁴⁷

The normal LV outflow tract has an angle of almost 90 degrees between the plane of the crest of the interventricular septum and the plane of the outlet septum. This angle is significantly decreased in AV canal defects, measuring 22 degrees in one study.⁴⁶ In the Rastelli C subtype, the angle is nearly normal after repair of complete AV canal, accounting for the decreased incidence of LVOTO in this setting.

The mechanism and severity of LVOTO usually can be delineated with two-dimensional echocardiography.

Cardiac catheterization is reserved to confirm the degree of obstruction, particularly in patients presenting late after AV canal repair.

The surgical treatment is usually determined by the mechanism of obstruction. Obstructing primary AV valve chordal attachments can be divided off the crest of the septum if they are secondary chordae. If the cleft is directed to the LV outflow, division of the chords and closure of the cleft usually treats the outflow obstruction. In tunnel-like LVOTO, more extensive enlargement of the LV outflow tract is required, such as a modified Konno procedure. Unlike the more common forms of tunnel-like LVOTO, in AV canal defects the conduction tissue is farther away from the area of enlargement, and injury to the AV node is rare. Subaortic obstruction may be recurrent. In one study of 19 patients with subaortic stenosis associated with AV canal defects,¹⁶ operations for LVOTO were performed.⁴⁶ The most common procedure was fibrous resection of a subaortic membrane with myectomy. Mean time to reoperation for recurrent LVOTO was 4.9 years, with a median follow-up period of 5.6 years. This resulted in a 6-year actuarial freedom from reoperation of 66%. To decrease the incidence of reoperation, leaflet augmentation with pericardium and fibromyotomy have been suggested.

Transposition of the Great Arteries

Management of TGA associated with complete AV canal defect is similar to the surgical treatment of each isolated defect. The AV canal defect is repaired, and an arterial switch procedure is performed. The AV canal repair is more challenging because valve leaflets are very friable in the first week of life compared with the first few months of life. All heart structures are smaller as well, which increases the technical complexity of the procedure. We recommend reinforcement of all sutures through AV valve leaflets with autologous pericardial pledgets, especially those placed for cleft closure. If the superior bridging leaflet is undivided, we recommend avoiding the classic single-patch technique because leaflet division is necessary. Resuspension of the leaflets onto the single patch may gather too much precious leaflet tissue, predisposing to the development of MR.

Double-Orifice Mitral Valve

Another unusual abnormality of the left-sided AV valve is double-orifice mitral valve, present in approximately 5% of cases. A second accessory orifice is present, usually on the inferior aspect of the left lateral leaflet, which can vary substantially in size. If the second orifice is small, it may be left open without consequence.

If large, the papillary muscles need to be examined because one papillary muscle may be related to each orifice, resulting in a parachute mitral valve of the major orifice. In these situations the cleft should be closed only partially, because postoperative mitral stenosis results with complete cleft closure. Splitting the bridging leaflet tissue between the two orifices is not advised; this can result in significant MR because the leaflet tissue becomes unsupported. In some cases, when regurgitation is present

at the accessory orifice, addition of a triangular patch made from glutaraldehyde-treated autologous pericardium has been advocated in an attempt to extend the width of the leaflets and improve coaptation.

Parachute Mitral Valve

A single papillary muscle is present in 5% of cases of complete AV canal defect. The presence of two closely spaced papillary muscles or a single papillary muscle can result in all chordal structures attaching to a single point, referred to as *parachute mitral valve*. Closure of the cleft between the LSL and LIL frequently results in postoperative mitral stenosis in this setting. We elect to leave the cleft either partially or fully open, depending on the degree of separation of the papillary muscles, the thickness of the chordae, and the width of the interchordal spaces. Rarely, this still results in significant regurgitation at initial operation. Techniques to split the papillary muscle improve leaflet mobility by separating the chordae. Similarly, when there are two separate but closely spaced papillary muscles, mobilizing the papillary muscles away from one another may be effective in improving the effective orifice of the mitral valve.

Unbalanced Atrioventricular Canal

Bharati and colleagues⁴⁸ pointed out that the AV junction may be committed primarily to one ventricle in some cases of complete AV canal defects, resulting in associated hypoplasia of the contralateral ventricular cavity and outflow structures. This occurs in approximately 5% to 7% of patients with complete AV canal defects. In the more common right ventricle–dominant form, there is significant hypoplasia of the left ventricle, aortic valve, ascending aorta, and aortic arch. Conversely, in the left ventricle–dominant type, hypoplasia of the right ventricle is seen.

Management decisions regarding the potential use of the hypoplastic chamber as part of a two-ventricle repair should be based on objective criteria quantifying absolute ventricular volumes indexed to body surface area. Measurement of relative ventricular cavity volume to compare RV and LV volumes is frequently unreliable. Absolute ventricular volumes with values of 15 mL/m² or greater are felt to be sufficient criteria for successful two-ventricle repair. Three-dimensional echocardiography has significantly improved ventricular volume measurements.

If the canal is only mildly unbalanced, then a two-ventricle repair can often be performed. If the canal is grossly unbalanced with severe hypoplasia of one ventricular cavity, then a single-ventricle approach may be followed. However, there is a growing experience with two-stage repair of unbalanced defects, with partial closure of the interatrial communication performed in the first stage to encourage ventricular growth. At the second stage, VSD closure is performed. Traditionally, criteria have been developed to decide between two-ventricle and single-ventricle management. They involve a determination of relative ventricular size, AV valve architecture and function, outflow tract size and position, and the presence of associated cardiac lesions:

FIGURE 116-12 ■ Proposed algorithm for management of unbalanced complete atrioventricular canal defects. AVV, Atrioventricular valve; AVVI, atrioventricular valve index; CAVVA, common atrioventricular valve area; L, left; LAVVA, left atrioventricular valve area; LV, left ventricle, PA, pulmonary artery; R, right; RV, right ventricle; UCAVC, unbalanced complete atrioventricular canal. (Adapted from Nathan M, Liu H, Pigula FA, et al: Biventricular conversion after single-ventricle palliation in unbalanced atrioventricular canal defects. *Ann Thorac Surg* 95:2086–2096, 2013.)

- The left ventricle reaches the apex or near the apex.
- The calculated postoperative LV volume is 15 mL/m² or greater.
- The calculated postoperative mitral valve annulus z-score is –2 or greater.
- Two papillary muscles are present, although a single papillary muscle is not an absolute contraindication for two-ventricle repair.
- AV valve chordae attaching to the conal septum, which is a substrate for LVOTO, are absent. Associated aortic coarctation is often present.
- Heterotaxy syndrome is absent, although rarely a patient with polysplenia has two well-balanced ventricles that are amenable to two-ventricle repair.

These criteria, however, do not account for the growth potential that exists, particularly in very young infants. Recent reports have described growth of the LV cavity after closure of interatrial communications by forcing blood flow across the left AV valve.⁴⁹ A study from Boston analyzed biventricular conversions after initial single ventricle palliation in 16 patients with unbalanced complete AV canal defects.⁵⁰ All patients had either unequal distribution of the common AV valve or hypoplastic ventricle. Eight patients were right dominant with median LV end-diastolic volume of 32 mL/m², and eight were left dominant with RV end-diastolic volume of 42 mL/m². Biventricular conversion was achieved in these patients

with two patient deaths and eight patient reinterventions in the study follow-up period. The algorithm proposed by these authors for management of unbalanced complete AV canal defect patients is shown in [Figure 116-12](#).

Heterotaxy Syndrome

There is a distinct group of patients with heterotaxy and AV canal defects. These patients are challenging to manage. The criteria for biventricular repair outlined here still apply to these patients. However, consideration needs to be given to septation of systemic and pulmonary venous return as well as repair of the common AV valve. Patients with complex anatomy may benefit from early single ventricle palliation and conversion to biventricular repair at older age.

Single Ventricle

When more complex malformations are present, such as severely unbalanced AV canal defects, consideration should be given to managing these patients along a single-ventricle pathway. In patients with complete AV canal defects and heterotaxy syndrome, associated conotruncal anomalies such as transposition and pulmonary stenosis or atresia are often treated with single-ventricle management.⁵¹

Recurrent Mitral Regurgitation

Significant postoperative MR requiring reoperation is present in 4% to 15% of patients after repair of AV canal defects.^{52,53} In our experience, those at highest risk had at least moderate MR early postoperatively.¹⁹ Other factors associated with progressive late postoperative MR include parachute mitral valve,⁵⁴ double-orifice mitral valve,^{19,55,56} absence of Down syndrome,²⁸ no closure of the cleft at primary repair,^{28,56,57} and preoperative MR.^{53,55} Although mild deterioration is fairly common after complete AV canal repair, serious deterioration is rare, especially after the first 30 postoperative months, as reported in one study of 39 patients.⁵⁸ Another study followed two groups of patients, one in whom the cleft was closed at the time of initial AV canal surgery, and the other in whom the cleft was deliberately left open as part of a trifoliate repair.⁵⁷ Overall survival and freedom from reoperation for MR were significantly better when the mitral valve cleft was closed at the time of initial AV canal surgery. One confounding variable was the earlier date of surgery in the group in whom the cleft was left open; improvements in myocardial preservation and postoperative care could have contributed to the improved results seen in the more recent group of patients in whom the cleft was closed.

The mechanism of late MR in the majority of cases has been regurgitation through the cleft, because it was either left open initially or reopened after complete or partial closure. Annular dilation with central regurgitation is frequently an associated finding. Worsening MR leads to worsening LV volume overload and eccentric LV hypertrophy, ultimately leading to LV dysfunction and failure. One study looked at the echocardiographic changes associated with left AV valve after complete AV canal repair, this study showed that a potential mechanism for recurrent MR could be due to annular dilation which occurs posteriorly toward the free wall.⁵⁹ This mechanism points to the beneficial effect of posterior annuloplasty performed at the time of original repair to lift the left lateral leaflet toward the septum and potentially to prevent development of MR.

Preoperative echocardiographic studies should delineate the mechanism of regurgitation and the location of the regurgitant jet (either centrally or through the cleft or both). A direct measurement of the diameter of the mitral annulus should be performed and compared with the expected annular diameter for the patient's age, corresponding to a z-score of 0.

Reoperative mitral valve repair depends on the underlying anatomic abnormality. If the regurgitation is through a cleft, then closure of the cleft, along with reduction of the mitral annular diameter to an appropriate size (z-score between -2 and +2), is often effective. More complex mechanisms such as immobile, thickened, or retracted mitral leaflets are more difficult to repair and frequently require leaflet augmentation with autologous pericardium, along with reduction of the annular diameter. The presence of MR thickens the leaflets, allowing closure of the tear either primarily or with a small pericardial patch. In the older child, a flexible partial annuloplasty ring should be implanted to provide support for the repaired valve, especially during ventricular systole.

In rare cases, mitral repair is not possible, and mitral valve replacement becomes necessary, typically using a mechanical prosthesis. Because the native left AV valve encroaches on the LV outflow tract, valve replacement can result in significant LVOTO. This can be avoided by first suturing a rectangular Dacron patch to the left AV valve annulus in the subaortic region. The mitral prosthesis can then be attached to the Dacron patch superiorly.⁶⁰ The conduction tissue is located at the anteroinferior aspect of the left AV valve annulus. The native AV valve leaflet tissue should be preserved in that location and not excised. Sutures can be passed through these native leaflets rather than through the mitral annulus in that location to minimize the incidence of heart block. Care should also be taken to avoid injury to the left circumflex coronary artery, which can be surprisingly close in small patients.

Outcomes after surgical management of recurrent MR are inferior to those reported after initial AV canal defects. In a study from our institution representing the largest series to date, 46 patients underwent reoperation between 1988 and 1998 for recurrent hemodynamically significant MR.⁴⁹ Survival at 10 years was 86.6%. Three of nine patients undergoing mitral valve replacement developed complete heart block. Significant improvements in clinical status were present after mitral valve surgery. Overall freedom from reoperation at 5 years was 78.5% for mitral valve repair and 85.7% for mitral valve replacement.

POSTOPERATIVE CARE

Postoperative management of patients after repair of complete AV canal defects is similar to the management of other patients after complex cardiac surgery. Intraoperative confirmation of complete closure of the VSD and ASD should be obtained. Our preference is to use measurements of right atrial and pulmonary artery oxygen saturations to detect residual left-to-right shunts. An increase in oxygen saturation greater than 10 mm Hg or an absolute pulmonary artery oxygen saturation greater than 80% while on 50% inspired oxygen suggests the presence of a hemodynamically significant residual VSD (i.e., ratio of pulmonary blood flow [Qp] to systemic blood flow [Qs], or Qp/Qs > 1.5). This should prompt intraoperative confirmation by echocardiography before a return to cardiopulmonary bypass and closure of the residual VSD.

Intraoperative transesophageal echocardiogram (TEE) is highly recommended for patients weighing more than 5 kg. TEE can be performed in patients as small as 2.5 kg, albeit with a higher risk of esophageal trauma and perforation coupled with a higher probability of left atrial compression by the posteriorly positioned TEE probe, which raises left atrial pressure. TEE is especially useful in evaluating AV valve function, particularly if significant MR is suspected. Monitoring left atrial and pulmonary artery pressures aids in the postoperative care of these patients, especially when preoperative pulmonary hypertension is present.

Low cardiac output state should be judiciously managed by aggressive use of inotropic support rather

than volume resuscitation, because excessive volume infusion can lead to ventricular distention and valvar dilation, resulting in worsening MR. The atrial filling pressures should be kept low, not significantly higher than 10 mm Hg, especially in the first 24 hours postoperatively. Use of afterload reduction, particularly with phosphodiesterase inhibitors such as milrinone, is particularly valuable in the early postoperative period. An aggressive search should be undertaken to exclude anatomic causes of low cardiac output syndrome.

Early postoperative pulmonary hypertension can be seen in patients with complete AV canal defects, and it is more prevalent with increasing age at the time of definitive repair and correlates with surgical mortality. Patients with Down syndrome usually have increased pulmonary artery pressure and increased pulmonary vascular resistance in the perioperative period.⁶¹ The insertion of a pulmonary artery line at the time of surgery aids in making the diagnosis. Anatomic causes that mimic pulmonary hypertension need to be excluded, such as severe MR, severe mitral stenosis, and residual VSD. Echocardiography is helpful in differentiating anatomic from nonanatomic causes of postoperative pulmonary hypertension.

OUTCOMES

Between January 1990 and December 1998, 365 patients with various forms of AV canal defects underwent two-ventricle repair at Children's Hospital Boston.⁶² Of these, 191 had a complete AV canal defect in which the VSD was deemed at least moderate in size and required patch closure. Among these 365 patients, 19 had associated TOF (5%) and 140 had either an ostium primum ASD alone or a transitional AV canal defect. Five patients had associated coarctation of the aorta, and seven had preoperative LVOTO. Trivial to mild AV valve regurgitation was present preoperatively in 159 patients (83%), and 26 (13%) had moderate to severe AV valve regurgitation. Of the patients with complete AV canal defects, 11% had at least moderate hypoplasia of one ventricle, 4% had a dominant left ventricle, and 7% had a dominant right ventricle.

The classic one-patch technique was used in 83% of the children with complete AV canal defects; the remaining 16% were repaired using the two-patch technique, depending on surgeon preference. The median age at repair was 4.6 months, and median weight was 4.5 kg.

In the 191 patients with complete AV canal defects undergoing biventricular repair, there were three early deaths, for an operative mortality of 1.5%. Three patients had complete heart block postoperatively, which required pacemaker insertion during the initial hospitalization. Trivial to mild MR was present on postoperative echocardiographic follow-up in 66% of the patients, whereas 10% had at least moderate MR at the time of discharge. There was no correlation between the presence of MR preoperatively and its presence postoperatively.

A review of 215 patients from the Pediatric Heart Network study examined outcomes and risk factors for development of MR across the various types of AV canal

repairs.⁶³ This study included 60 patients with partial AV canal, 27 with transitional AV canal, 120 with complete AV canal, and 8 with canal-type VSD. Independent risk factors for moderate to severe MR at 6 months after surgery included older age at repair and presence of moderate or greater MR on the immediate postoperative echo. This study did not show any significant benefits of annuloplasty performed at time of original repair.

Complete Atrioventricular Canal Defect

Several factors have contributed to decreasing mortality for repair of complete AV canal defects over the past two decades. Mortality ranges between 0.5% and 13% in various studies.^{27,64,65} Risk factors that affect overall survival and the need for reoperation include the following:

- *Earlier era of operation:* This has been a consistent risk factor for both early death and late reoperation in a variety of studies.^{19,65-67} Improvements in myocardial preservation, intraoperative anesthetic management, perfusion methods, intraoperative TEE, postoperative care, and better understanding of lesion anatomy, along with better surgical techniques, have contributed to decreasing mortality over time.
- *Older age at surgery:* Repair beyond age 3 to 4 months has been correlated with increased perioperative mortality.^{31,55} This may be related to the higher incidence of pulmonary hypertensive crises seen with increasing patient age at the time of definitive surgery.⁶⁸ Postoperative pulmonary hypertensive crises have been correlated with increased operative mortality and need for reoperation.^{27,66} Increasing age as a risk factor for mortality has not been shown to be the case in all studies.^{67,69} In fact, in one study of 274 patients, repair at less than 6 months of age was an incremental risk factor for perioperative mortality.⁶⁷
- *Postoperative left AV valve regurgitation:* This has been identified in most series to be a key risk factor for the subsequent need for reoperation^{56,66,70,71} and death.^{19,66} The overall incidence of significant postoperative MR has slowly decreased over the years as surgical techniques have improved and a better understanding of the underlying anatomy has evolved. A review from our institution revealed a reoperation rate of 7% in recent years.¹⁹ Other contemporary series have noted an incidence of 16% for at least moderate postoperative MR.⁷²
- *Preoperative AV valve regurgitation:* A higher incidence of postoperative MR is seen in patients with higher degrees of preoperative AV valve regurgitation.⁷² Leaflet division may exacerbate this association.⁷² This has not been a consistent finding, with one recent study of 115 patients reporting that moderate to severe preoperative left AV valve regurgitation, present in 21 patients, was not a risk factor for operative mortality.⁶⁵ In the same study, moderate or severe late MR was present in 17% of patients with mild or less preoperative left AV valve regurgitation compared with 33% of patients with

moderate or severe preoperative left AV valve regurgitation, although this difference was not statistically significant. An earlier study of 62 infants operated on before 1987 also failed to show the correlation between preoperative and postoperative MR.²⁸

- *Double-orifice mitral valve:* This adversely affects both survival and freedom from reoperation. It may be associated with unbalanced AV canal with RV dominance, a single papillary muscle, LVOTO, and aortic coarctation. If the cleft is closed completely, postoperative mitral stenosis can result. Some have recommended leaving a fenestration in the interatrial septum to allow decompression of the left atrium as needed.⁵⁶

Partial Atrioventricular Canal Defect

The operative mortality for partial AV canal defects is low—less than 1% in most series. A small subset of patients display heart failure symptoms and several left-sided obstructive lesions within the first year of life.³³ These patients represent a higher-risk subgroup. In a study of 180 patients repaired between 1982 and 1996,⁵³ early mortality was 1.6%. The mean age at repair was 4.6 years; repair at less than 1 year of age was a significant risk factor for mortality. With a mean follow-up period of 6 years, 10-year actuarial survival was 98%. Important long-term sequelae were the development of late MR and subaortic obstruction.

Similar findings were reported in 2000 in the largest series to date of patients with ostium primum ASD.⁷³ A total of 334 patients who underwent repair over a 40-year period between 1955 and 1995 were studied, with a median follow-up period of 19 years. The 30-day perioperative mortality was 2%, whereas 20- and 40-year survival rates were 87% and 76%, respectively. Although this long-term survival was good, it was lower than that for the general population. Reoperation occurred in 11% of patients, most commonly for mitral stenosis or MR. LVOTO occurred in 11% of patients ($n = 36$), although only seven patients required reoperation. Postoperative supraventricular arrhythmias were common, especially in older patients. Although the study was descriptive, with important limitations with respect to data collection and analysis, it does provide long-term insight regarding outcomes in these patients.

Late MR, although rare, correlates with late morbidity, similar to the situation for complete AV canal defects. In partial AV canal defects, the incidence of significant MR requiring reoperation ranges between 7% and 10%, depending on the study and the length of follow-up.⁷⁴ This may be correlated with a more frequent need for valve replacement than in complete AV canal defects,^{74,75} possibly related to the fixation of the superior leaflet to the crest of the interventricular septum and the association of subvalvar abnormalities.

SUMMARY

Atrioventricular canal defects represent a continuum of lesions with varying degrees of AV valvar abnormalities

and interatrial and interventricular communications. In complete AV canal defects, complete elective repair should be performed early in infancy, preferably between 2 and 4 months of age. Equivalent results have been obtained with the three standard techniques of repair. Surgical intervention results in low mortality and morbidity, in both the short and the long term. When congestive heart failure or moderate to severe MR is present, complete repair should be undertaken at the time of presentation, because further delay or use of palliative procedures only increases the risks of subsequent definitive surgical therapy.

Surgical management of transitional and partial AV canal defects should include elective repair in early childhood. When left AV valve regurgitation is significant, repair should be undertaken earlier to prevent further deterioration of valve function and LV dilation and dysfunction.

Associated cardiac surgical lesions should be repaired at the time of complete AV canal repair. A remaining management dilemma is the patient with unbalanced AV canal defect, where surgical options include biventricular correction versus univentricular palliation.

Outcomes of patients with complete AV canal defects have improved steadily over the years. This reflects not only better intraoperative management, but also improved preoperative and postoperative care and follow-up in these patients.

VENTRICULAR SEPTAL DEFECT

A ventricular septal defect (VSD) is a hole between the left and right ventricles. A VSD may occur as an isolated anomaly or with a wide variety of intracardiac anomalies, such as tetralogy of Fallot or transposition of the great arteries. This chapter discusses isolated VSD.

Banding of the pulmonary artery as a palliative maneuver was first described in 1952.¹ This decreased left-to-right shunting and as a consequence prevented the development of pulmonary vascular obstructive disease and left-sided volume overload. Until the mid-1960s when primary VSD closure became safer, pulmonary artery banding was the procedure of choice in managing VSDs. The first VSD closure was performed in 1955 by Lillehei and associates² at the University of Minnesota, using

controlled cross-circulation between the child and parent. Nineteen of the 27 patients who underwent this procedure survived. In 1957, Kirklin and associates³ at the Mayo Clinic closed a VSD using a heart-lung machine. In 1957, transatrial VSD closure was performed,⁴ followed in 1971 by the popularization of primary repair in symptomatic infants by Barratt-Boyes and associates⁵ using cardiopulmonary bypass, deep hypothermia, and circulatory arrest.

Anatomy

Anatomy of the Tricuspid Valve, Right Ventricular Septum, and Conduction System

Surgeons planning VSD surgery must have intimate knowledge of the tricuspid valve, the right ventricular septal anatomy, and the conduction system.

FIGURE 117-1 ■ The components of the ventricular septum as seen from the right ventricle (A) and the left ventricle (B). (Modified from Soto B, Becker AE, Moulart AJ, et al: Classification of ventricular septal defects. *Br Heart J* 43:332–343, 1980.)

The tricuspid valve has three leaflets: anterior, septal, and posterior. The anterior leaflet is connected via the chordae tendineae cordis to the anterior papillary muscle (located on the anterior right ventricular free wall) and to the septal papillary muscle (sometimes called muscle of Lancisi). The septal papillary muscle is itself part of the septal band of the septomarginal trabecula. The posterior leaflet is attached to the anterior and posterior papillary muscles, and the septal leaflet attaches to the posterior and septal papillary muscles.

The right ventricular septum has five components (Fig. 117-1):

1. The membranous septum
2. The atrioventricular (AV) canal or inlet septum
3. The muscular septum (apical trabecular septum or sinus septum)
4. The trabecula septomarginalis (septal band and moderator band)
5. The conal septum (infundibular septum and parietal band)

Unlike the left ventricular septum, which is free of any papillary muscle attachment (the mitral valve can be called “septophobic,” whereas the tricuspid valve can be called “septophilic”), the right ventricular septum is where the septal (sometimes called medial) papillary muscle and part of the posterior papillary muscle originate. The septal papillary muscle is a portion of the septal band, which runs along the septum (hence its name). The septal band is a portion of the septomarginal trabecula, which also includes the moderator band. The moderator band links the septum to the anterior papillary muscle (called moderator band because it was erroneously thought to “moderate” the right ventricular free wall—that is, keep in sync with the rest of the ventricle). The membranous septum is the only fibrous component of the septum. It is wedged between the aortic valve, the tricuspid valve, and the mitral valve. Because the tricuspid valve is normally apically displaced vis-à-vis the mitral valve, a portion of membranous septum ends up between the right atrium and the left ventricle, called the AV part of the membranous septum. The portion of membranous septum located between both ventricles is called the interventricular part.

Knowledge of the conduction system of the heart also is critical when approaching VSDs so as to avoid damaging it (Fig. 117-2). The various atrial conduction tracts all converge toward the AV node of Aschoff-Tawara. The AV node is located in the inferior-posterior portion of the membranous septum, just inferior to the antero-septal commissure of the tricuspid valve. A different description of its location is that it occupies the apex of the triangle of Koch, which is limited by the ligament of Todaro posteriorly, the orifice of the coronary sinus inferiorly, and the tricuspid valve annulus superiorly (see Fig. 117-2). From the AV node, the common AV bundle of His descends within the interventricular part of the membranous septum (or, in the case of a membranous VSD, the posteroinferior rim of the VSD), traverses the septum, and then courses along the left ventricular aspect of the septum. It then separates into a right bundle branch, which travels back to the right ventricular surface, as well as a left bundle branch. At the anteroinferior border at the level of the muscle of Lancisi, the right bundle branch descends toward the right ventricular apex.

Anatomic Classification of Ventricular Septal Defects

A useful surgical classification of VSDs was initially developed in 1980 by Soto and associates⁶ (Fig. 117-3) and then further modified by Van Praagh and associates (Fig. 117-4).⁷ Variations of this classification are used in most pediatric cardiac centers. VSDs can be classified as follows:

- Conoventricular (or membranous) defects
- Conal (or outlet) VSDs
- Inlet (or AV canal type) VSDs
- Muscular VSDs (single or multiple)

Conoventricular (or Membranous) Defects. Conoventricular defects are located between the conal septum and the ventricular septum. They are centered around the membranous septum and comprise 80% of all VSDs. They may be located exclusively in the membranous septum, or they can extend beyond the boundaries of the membranous septum in the inferior, posterior, or anterior direction and are then sometimes called perimembranous or paramembranous VSDs. The prefix *peri-*, appearing in loan words from the Greek, means “surrounding” (e.g., perimeter). Thus, a truly perimembranous VSD would surround the membranous septum. In contrast, the prefix *para-*, also from the Greek, means “adjacent to” or “beside” and more accurately reflects the notion of a defect adjacent to the membranous septum. Neither *perimembranous* nor *paramembranous* correctly describes the typical defect involving the membranous septum and extending into the adjacent septum. The current recommendation is to call these defects either membranous VSDs or conoventricular defects. Malalignment of the conal septal plane vis-à-vis the ventricular septal plane results in the typical conoventricular defect. The malalignment can be anterior, as seen in tetralogy of Fallot, for example, or posterior, as seen in interrupted aortic arch. In addition to resulting in a VSD, anterior conal septal malalignment also results in right

FIGURE 117-2 ■ Schematic representation of the conduction system. **A**, The atrioventricular (AV) node lies embedded within the triangle of Koch, close to the orifice of the coronary sinus and between the annulus of the tricuspid valve and the tendon of Todaro. The bundle of His originates from the AV node, extends toward the commissure between the septal and anterior leaflets of the tricuspid valve, and penetrates along the posteroinferior margin of the membranous septum and across the muscular ventricular septum. **B**, The bundle of His gives rise to the left posterior branch (LPB) and the left anterior branch (LAB). The right bundle branch (RBB) then travels back along the ventricular septum toward the right ventricular septal surface. At the level of the muscle of Lancisi, the right bundle branch descends toward the right ventricular apex. (Modified from Castaneda AR, Jonas RA, Mayer JE Jr, et al: Double outlet right ventricle. In Castaneda AR, Jonas RA, Mayer JE Jr, et al, editors: *Cardiac surgery of the neonate and infant*, Philadelphia, 1994, WB Saunders, pp 445–449.)

FIGURE 117-3 ■ Classification of ventricular septal defects according to their location in the septum. (Modified from Soto B, Becker AE, Moulart AJ, et al: Classification of ventricular septal defects. *Br Heart J* 43:332–343, 1980.)

ventricular outflow tract obstruction, whereas posterior malalignment of the conal septum results in left ventricular outflow tract obstruction. Important landmarks in conoventricular septal defects are the anterosseptal commissure of the tricuspid valve inferiorly and the noncoronary cusp of the aortic valve. When the ventricular portion of the membranous septum is entirely absent, the VSD extends to the base of the aortic valve (sometimes called subaortic VSD). The medial papillary muscle (muscle of Lancisi) located at the inferoposterior border

FIGURE 117-4 ■ Classification of ventricular septal defects (VSDs): atrioventricular canal type; muscular VSDs (anterior [1], midventricular [2], posterior [3], and apical [4]); conoventricular septal defect, which includes paramembranous and malalignment conoventricular septal defects; and conal septal defects. (Modified from Castaneda AR, Jonas RA, Mayer JE Jr, et al: Double outlet right ventricle. In Castaneda AR, Jonas RA, Mayer JE Jr, et al, editors: *Cardiac surgery of the neonate and infant*, Philadelphia, 1994, WB Saunders, pp 445–449.)

of the defect is also an important landmark. Both the septal and the anterior tricuspid valve leaflets are attached to it.

Conal Ventricular Septal Defects. Approximately 8% of VSDs are located in the conal (infundibulum or outlet)

septum. They also are called supracristal VSDs. They are either entirely surrounded by muscle (muscular conal VSDs) or limited upstream by the aortic or pulmonary annuli (sometimes called subarterial VSDs).

Inlet (or Atrioventricular Canal Type) Ventricular Septal Defects. Inlet VSDs are characterized by the absence of part or all of the AV canal (inlet) septum. These VSDs are located immediately underneath the septal leaflet of the tricuspid valve, with no tissue in between. Approximately 6% of all VSDs are inlet-type VSDs.

Muscular Ventricular Septal Defects. Muscular VSDs (10% of all VSDs) are entirely surrounded by muscle. They can occur anywhere in the trabecular portion of the septum and can be isolated or multiple. They are described by their location—that is, anterior, midventricular (between the muscular septum and the septal band), posterior, or apical. When inspected through the left side of the septum, what appeared to be multiple muscular defects often converge into either a single hole or two separate holes.

Commonly Associated Defects

VSDs are an intrinsic portion of many, if not most, complex cardiac malformations. These VSDs are discussed separately with their respective entities (see other chapters). Almost half of patients who undergo surgical treatment of primary VSD have an associated lesion.

A large patent ductus arteriosus (PDA) is present in approximately 25% of symptomatic neonates and infants with VSDs.⁵ This is important to know because preoperative echocardiography may fail to show a PDA in the presence of a large amount of left-to-right shunting. Furthermore, intraoperative transesophageal echocardiography (TEE) is notoriously unreliable in excluding PDAs. Therefore the possibility of a PDA should be kept in mind when approaching a VSD, and if there is any doubt, or if there is a large amount of backflow through the pulmonary arteries on cardiopulmonary bypass, the PDA should be ligated or clipped.

A hemodynamically significant aortic coarctation is present in approximately 10% of cases. Because of the unique pathophysiology of aortic coarctation (more left-to-right shunting across the VSD because of increased afterload caused by the coarctation), these patients usually have presenting symptoms before 3 months of age.⁸

Congenital valvar or subvalvar aortic stenosis, resulting in left ventricular outflow tract obstruction, is seen in approximately 4% of patients requiring an operation for a VSD.⁹ The most common type of subaortic stenosis associated with VSDs involves the discrete fibromuscular membrane of the VSD that is located inferior or upstream to it. Congenital mitral valve stenosis is rare and occurs in approximately 2% of patients.

Other significant anomalies include large atrial septal defects (ASDs), right ventricular outflow tract obstruction, vascular ring, and persistent left superior vena cava.

Pathophysiology

Shunt Direction and Magnitude

The magnitude and direction of the shunt across a VSD depend on the size of the defect and the pressure gradient across it during the various phases of the cardiac cycle. Large VSDs offer little or no resistance to blood flow and are therefore called nonrestrictive. The right ventricular pressure equals the left ventricular pressure, and the ratio of pulmonary to systemic flow (Q_p/Q_s) (or shunt) is dependent on the ratio of pulmonary vascular resistance (PVR) to systemic vascular resistance (SVR). On the other hand, small VSDs offer resistance to flow across the defect and are therefore termed restrictive VSDs. The Q_p/Q_s rarely exceeds 1.5. Moderate-sized VSDs fall between these two categories and the Q_p/Q_s usually ranges between 2.5 and 3. To a lesser degree, further determinants of shunt magnitude also include the relative compliance of both ventricles and the pressure relationships during the various phases of the cardiac cycle. The size of the VSD—in particular, of muscular VSDs—also may vary during various phases of the cardiac cycle. Because the PVR is elevated during the first few weeks of life, it is unusual to have to close an isolated VSD. As the PVR falls with increasing age, left-to-right shunting increases, necessitating treatment.

Sequelae of Left-to-Right Shunting

Left-to-right shunting at the ventricular level implies increased pulmonary blood flow. Therefore, left ventricular preload is similarly increased, resulting in increased workload for both left and right ventricles. The left atrium is enlarged, and the left atrial pressure is elevated. The left ventricle dilates. The raised left atrial pressure causes many infants with VSD to have an increased accumulation of interstitial fluid in the lungs, resulting sometimes in repeated pulmonary infections. The work of breathing is increased as the lung compliance is decreased. This increases energy expenditure, which, along with the relatively low systemic blood flow, causes these infants to have striking failure to thrive. When pulmonary resistance rises as a result of the development of pulmonary vascular disease, pulmonary blood flow is reduced and the child appears to improve. Unfortunately, further increases in PVR occur, and the classic Eisenmenger complex results. These patients are characterized by fixed pulmonary hypertension, bidirectional shunting, right ventricular hypertrophy, and a normal-sized left ventricle. They are often inoperable and require heart-lung transplantation for further survival.

Pulmonary Vascular Disease

The classic description of the pathology of hypertensive pulmonary vascular disease is that of Heath and Edwards.¹⁰ They correlated the PVR of patients with large VSDs with the histologic severity of pulmonary vascular changes. Grade 1 changes were defined as medial hypertrophy without intimal proliferation; grade 2 as medial hypertrophy with cellular intimal reaction; grade 3 as

intimal fibrosis and medial hypertrophy; grade 4 as generalized vascular dilation, an area of vascular occlusion by intimal fibrosis, and plexiform lesions; grade 5 as other "dilation lesions" such as cavernous and angiomatoid lesions; and grade 6 as necrotizing arteritis. It is assumed that Heath-Edwards grade 3 or greater is not reversible. The importance of lung biopsies has decreased over the years, with catheterization-based data increasing in importance in terms of suitability for repair.

Natural History and Indications for Surgery

Approximately 30% of infants with severe symptoms such as intractable congestive heart failure or failure to thrive require surgery within the first year of life.¹¹ The remainder can usually be managed medically, because the natural history of VSDs is well known.¹² Aggressive medical management is indicated because most membranous and muscular VSDs tend to close spontaneously.¹² Malalignment conoventricular VSDs or inlet-type VSDs are unlikely to close spontaneously, and therefore closure at the time of diagnosis is recommended, regardless of age or weight. Asymptomatic children with isolated small restrictive VSDs can be followed safely with serial echocardiograms.

The development of pulmonary vascular disease is a tragedy that can be prevented with virtually no mortality by VSD closure. If in doubt, cardiac catheterization and measurement of PVR-to-SVR ratio should help with decision making. In addition, pulmonary artery (PA) pressures greater than one half the systemic pressure in a child older than 1 year indicate the need for surgery. If PA pressures are greater than one half the systemic, the response of the pulmonary vasculature to inhaled nitric oxide and 100% inspired oxygen should be studied during catheterization. Even children who have significant pulmonary hypertension with a reversible component to it can become operative candidates.

During the first decade of life, a small proportion (5%) of patients with membranous or outlet VSDs develop prolapse of an aortic cusp into the VSD. This usually results in a gradual decrease of the effective orifice and shunt flow and also in increasing aortic regurgitation. Increasing aortic cusp prolapse and regurgitation are an indication to operate.

Diagnosis and Workup

Results of the physical examination, chest radiograph, and electrocardiogram (ECG) depend on the underlying pathophysiology. Patients with large VSDs and increased pulmonary blood flow usually have symptoms such as tachypnea, growth failure, profuse sweating during feeding, a bulging precordium, a pansystolic murmur, an enlarged liver, and thready pulses. The chest film shows a large central and peripheral PA and enlarged left atrium and ventricles (Fig. 117-5). ECG shows signs of biventricular enlargement. In contrast, patients with small VSDs and small left-to-right shunts have only a systolic murmur. The chest radiograph and ECG may be entirely normal (Fig. 117-6). Two-dimensional echocardiography

FIGURE 117-5 ■ Chest radiograph of a child with a large ventricular septal defect, large pulmonary blood flow, and pulmonary hypertension, but only mildly elevated pulmonary vascular resistance, as indicated by left and right ventricular enlargement, enlargement of the main pulmonary artery, and a sharp increase in pulmonary vascular pattern.

and color flow Doppler studies have essentially replaced cardiac catheterization in most patients with isolated VSDs. Cardiac catheterization is needed only when PVR and PA pressure need to be measured.

Surgical Technique

For closure of conoventricular septal defects, the PDA is routinely dissected and ligated as soon as cardiopulmonary bypass is instituted. The left branch PA and distal aortic arch should be positively identified before ligation. Moderate hypothermia (rectal temperature, 28° C to 32° C) is usually sufficient. Small infants weighing less than 2.5 kg may require lower temperatures (18° C to 25° C) to safely institute low-flow bypass. Deep hypothermic circulatory arrest is rarely used for closure of VSDs. After cross-clamping the aorta and delivering the cardioplegia solution, the caval tapes are tightened. A right atriotomy approach is preferred for most VSDs. The atrium is opened obliquely (Fig. 117-7) to avoid the area of the sinus node. The atrial septum is inspected first, and if a patent foramen ovale (PFO) is present, a left atrial sucker can be placed. Retraction of the septal and anterior leaflets of the tricuspid valve usually provides adequate exposure. The area located behind the antero-septal commissure of the tricuspid valve often is the most difficult to expose. If the tricuspid valve attachments are in

FIGURE 117-6 ■ In contrast to the heart shown in Figure 117-5, the heart in this chest radiograph is not enlarged overall. The main pulmonary artery is enlarged, but there is no evidence of increased pulmonary blood flow. This patient has a large ventricular septal defect, pulmonary hypertension, severe elevation of pulmonary vascular resistance, and pulmonary blood flow that is less than systemic blood flow. The condition is inoperable and usually requires a heart-lung transplant or a lung transplantation with concomitant intracardiac repair. (Modified from Dushane JW, Kirklin JW: Selection for surgery of patients with ventricular septal defects and pulmonary hypertension. *Circulation* 21:13, 1960; with permission of the American Heart Association, Inc.)

the way, the surgeon can detach the septal or anterior leaflet by making an incision that parallels the tricuspid annulus (see Fig. 117-7). Some surgeons perform this maneuver routinely. If VSD exposure remains poor despite rearranging the field, an infundibular incision is the usual fallback option for exposure. Interrupted mattress or running nonabsorbable sutures are used. Teflon pledgets are very useful in neonates and infants, in whom the myocardium is friable. The first suture is usually placed into the midportion of the defect, approximately 3 mm from the rim of the defect. When the inferior margin is reached (at approximately the level of the muscle of Lancisi), sutures should be placed farther away from the edge and become more superficial. At the tricuspid annulus, sutures are passed through its fibrous tissue. Because conduction tissue is composed of specialized muscle cells, fibrous tissue offers a safe area to place sutures. There is usually very little tissue separating the aortic valve from the posterosuperior margin of the defect. Therefore, several sutures are usually placed from the right atrial side through the tricuspid valve annulus to avoid damage to the aortic valve cusp. Infusion of cardioplegic solution fills the aortic root and allows accurate delineation of the insertion of the aortic valve cusps. All sutures are then passed through an appropriately tailored patch (Dacron, Gore-Tex, or pericardium) and tied in place. The tricuspid valve should be routinely inspected

and passively inflated with saline to ensure that no significant tricuspid valve regurgitation has been inadvertently created.

For closure of an AV canal type of VSD (Fig. 117-8), exposure is usually straightforward. A continuous suture technique is often preferred, because it allows weaving in and out between the various chordae and papillary muscles that usually crowd the edge of these defects. To avoid damage to the bundle of His and the right bundle branch that course along the posteroinferior edge, stitches in that area are placed farther away from the edge of the VSD.

For closure of conal VSDs (Fig. 117-9), exposure is obtained through the infundibulum, the pulmonary artery, or the aorta. Often no muscle lies between the superior edge of the defect and the pulmonary valve. Again, it can be useful to fill the aortic root with cardioplegic solution to determine the exact position of the cusps. The initial sutures are placed either within the fibrous rim separating the two semilunar valves or within the left and right pulmonary sinuses of Valsalva. The remaining sutures can be placed with no fear of injury to the conduction tissue as it travels farther caudally between the infundibular and trabecular ventricular septum.

The approach used in closure of muscular VSDs depends on their location. Mid-muscular defects are preferably closed through a right atriotomy. A single patch can cover several separate defects. Posterior muscular defects are hidden behind the posterior leaflet of the tricuspid valve. Anterior muscular defects are often difficult to find, because they are hidden behind the septal band and hypertrophied trabeculae of the right ventricular free wall. It is important to divide the muscle bundles that bind the septal band to the septum to adequately expose the true margins of the VSD. A patch is used, and the surgeon must pay close attention to avoid distortion of the left anterior descending coronary artery. Apical defects can also be difficult to expose. The coarse trabeculations located in the right ventricular apex make the exact determination of the true margins difficult. An apical right ventriculotomy is extremely helpful and virtually always allows good exposure of the apical muscular septum. Left ventricular apical incisions are essentially obsolete because of the high prevalence of left ventricular dyskinesia and apical aneurysms after this incision. Percutaneous transcatheter closure of muscular VSDs with occluding devices is another approach for patients with apical VSDs or multiple muscular VSDs. When the percutaneous approach is not possible, intraoperative deployment of a device on the beating heart via a right ventricular puncture can be used.¹³

Surgical Management of Ventricular Septal Defect with Associated Anomalies

The vast majority of patients who have VSD with coarctation of the aorta are young infants. The traditional approach has been to simultaneously repair the coarctation and band the pulmonary artery. This evolved into aortic coarctation repair followed by VSD repair during the same hospitalization, if symptoms of heart failure persisted, in the form of failure to extubate, for example.

FIGURE 117-7 ■ Trans-right atrial exposure of conoventricular ventricular septal defect (VSD). **A**, Incision in the right atrium. **B**, Exposure of conoventricular VSD with retraction of the anterior and septal leaflets of the tricuspid valve. **C**, Sutures 1, 2, 3, and 4 are placed in the ventricular septal wall, approximately 3 mm from the rim of the defect. **D**, Suture 5 is placed where the leaflet fuses with the crest of the VSD, and sutures 6, 7, and 8 are passed from the right atrial side through the tricuspid annulus; the rest of the sutures are placed in the anterosuperior rim of the VSD. **E**, Completed closure of the VSD with a Dacron patch and pledgeted sutures. **F**, If chordae and papillary muscles obliterate the view of the VSD, the septal and anterior leaflets of the tricuspid valve are incised along the base, permitting complete exposure of the VSD. **G**, Septal and anterior leaflets of the tricuspid valve are resutured after closure of the VSD with a patch. (Modified from Castaneda AR, Jonas RA, Mayer JE Jr, et al: Double outlet right ventricle. In Castaneda AR, Jonas RA, Mayer JE Jr, et al, editors: *Cardiac surgery of the neonate and infant*, Philadelphia, 1994, WB Saunders, pp 445–449.)

FIGURE 117-8 ■ Closure of atrioventricular (AV) canal type of ventricular septal defect (VSD). **A**, Transatrial view of AV canal type of VSD. **B**, Retraction of the septal leaflet of the tricuspid valve exposes the defect to the tricuspid valve annulus. **C**, Closure of AV canal defect with the continuous suture technique. (Note the continuous horizontal mattress suture with the septal leaflet tissue and also the interrupted horizontal mattress sutures along the posteroinferior portion of the VSD, placed approximately 4 mm from the VSD to avoid damage of the conduction bundle.) **D**, If dense chordae obstruct the view of the defect, the septal leaflet of the tricuspid valve is incised along its base, providing exposure of the entire circumference of the AV canal type of VSD. **E**, Patch closure of the AV canal type of VSD. **F**, The incised leaflet is reattached with continuous suture. (Modified from Castaneda AR, Jonas RA, Mayer JE Jr, et al: Double outlet right ventricle. In Castaneda AR, Jonas RA, Mayer JE Jr, et al, editors: *Cardiac surgery of the neonate and infant*, Philadelphia, 1994, WB Saunders, pp 445–449.)

As techniques for complex neonatal repairs matured and results improved, many centers have come to favor a single-stage method of simultaneously repairing the coarctation and the VSD via a midline approach.⁸ Of course, this is done only if the VSD is judged not likely to close spontaneously, whether by size or location.

Patients who have VSD with aortic insufficiency are usually older children. The right or noncoronary cusp is prolapsing into the VSD secondary to the Bernoulli effect. When there is mild to mild-moderate aortic

regurgitation with little scarring or fibrosis of the cusps, VSD closure alone is required. Patients with more than moderate aortic incompetence and cusp retraction usually require commissural resuspension of the affected cusp via an aortotomy (see [Chapter 123](#)).

Patients with VSD with prior banding are most often those with multiple muscular VSDs. The resulting right ventricular hypertrophy makes the intraoperative identification of these VSDs even more difficult. Intraoperative device closure via right ventricular puncture has been

FIGURE 117-9 ■ Transventricular approach to closure of conal ventricular septal defect. **A**, Commonly there is no intervening muscle between the superior edge of the defect and the pulmonary valve. **B**, Initial sutures placed in the fibrous rim separating the two semilunar valves. **C**, If the area between the aorta and the pulmonary cusps is tenuous, interrupted pledgeted mattress sutures are passed within the right and left pulmonary sinuses. **D**, The Dacron patch is anchored to the remainder of the ventricular septal defect with a continuous suture. (Modified from Castaneda AR, Jonas RA, Mayer JE Jr, et al: Double outlet right ventricle. used successfully, along with removal of the PA band and PA plasty in one setting.¹³

Postoperative Care

Most infants convalesce normally after VSD repair, and special treatment is usually not required. Patients are generally extubated within 24 hours of surgery and

recover rapidly. In the unusual case of low cardiac output after surgery despite the usual supportive treatment, it is the surgeon's responsibility to prove that there are no technical issues causing the unusual postoperative course. Problems could include a large residual VSD, injury to the aortic cusp that occurred during suture placement, or tricuspid regurgitation. Bedside echocardiography usually quickly diagnoses these problems. If

complete AV dissociation occurs after cardiopulmonary bypass, temporary pacing wires are used until sinus rhythm reappears. AV block can last up to 10 to 14 days, beyond which time it is usually permanent and a permanent pacemaker should be placed.

Pulmonary hypertensive crisis is a severe postoperative complication that can occur in older patients with a reactive pulmonary vasculature. If the patient is at risk, then, in the operating room, a pulmonary arterial line should be placed, introduced either via an infundibular puncture or under direct vision via the right atrium. A pulmonary hypertensive crisis can occur without a precipitating factor; however, tracheal suctioning, respiratory or metabolic acidosis, hypoxemia, and high-dose inotropes can be precipitating factors. Patients benefit from increased sedation, muscular paralysis, and hyperventilation with a high level of inspired oxygen. Inhaled nitric oxide, at dosages ranging from 5 to 40 ppm, is the preferred agent in managing pulmonary hypertension. Ideally, it is started prophylactically in the operating room as soon as ventilation resumes, while the patient is still on cardiopulmonary bypass.¹⁴

Results of Surgical Treatment

Early Results. Because of improvements in intraoperative and postoperative management and minimization of human error, the hospital mortality rate for repair of isolated VSD now approaches 0% in most experienced pediatric cardiac centers. Since the late 1980s, along with marked improvement in survival after complex neonatal cardiac surgery, very low-weight or very young infants with isolated VSDs also have a mortality rate of less than 5%.¹⁵ Prematurity, significant preexisting respiratory problems such as bronchopulmonary dysplasia, or unrecognized respiratory syncytial virus infection increases morbidity and mortality slightly but not significantly. In an operable patient, elevated PVR is a risk factor for complications or prolonged hospital stay, but it is not a determinant of hospital mortality. Unrecognized additional cardiac lesions can lead to significant problems if reoperation is required. Although complete AV dissociation is uncommon after isolated VSD repair, it remains a complication that occurs in 0.5% to 3% of patients after VSD closure. Right bundle branch block occurs in most patients after VSD closure and is usually very well tolerated. Its implications in the long term are unclear. Significant residual postoperative left-to-right shunting is uncommon when proper techniques are used. Most frequently it results from suture dehiscence, seen most often in small infants with friable myocardium. When it is hemodynamically significant, reoperation should be performed expeditiously. When the patient is asymptomatic and progressing well during the postoperative course, the leak is usually smaller, and the surgeon may elect to observe the patient with serial echocardiograms for a period of several weeks. Most small residual VSDs (<3 mm) close spontaneously over a period of months because of scar formation at the edge of the patch.

Late Results. Repair of VSD in the first year or two of life cures most patients and results in full functional

activity and normal or almost normal life expectancy. Normal or near-normal long-term growth and cardiac function are expected in most patients.¹⁶ Late deaths virtually never occur in patients with normal or near-normal PVR. Detailed studies of PA pressure and PVR were performed in infants undergoing VSD closure at the Boston Children's Hospital, where 96% of infants had a mean PA pressure of greater than 40 mm Hg, and 51% continued to have elevated PA pressures at 24 hours postoperatively. Postoperative catheterization studies done 1 year later showed that PA pressure in this group had decreased to a mean of 14 mm Hg.^{17,18} Severe pulmonary hypertension postoperatively can increase with time and cause premature death, usually within 3 to 10 years after the operation. Other patients with pulmonary hypertension have a stabilization of their pulmonary vascular process, with neither increase nor decrease of the PVR. They usually have limitations in their exercise tolerance. In a study of 296 surviving patients after VSD closure followed for 30 to 35 years postoperatively, higher mortality was observed in those who underwent surgery after the age of 5 years, in those with PVR greater than 7 U/m², and in those with transient or permanent complete heart block.¹⁹

DOUBLE-OUTLET RIGHT VENTRICLE WITH NORMALLY RELATED GREAT ARTERIES

Simply defined, double-outlet right ventricle (DORV) refers to a heterogeneous group of cardiac malformations in which both great arteries arise from the right ventricle.^{4,7} Although the term DORV can be correctly applied to single-ventricle hearts or hearts with AV discordance (e.g., congenitally corrected transposition of the great arteries), for simplicity of discussion, only hearts with AV concordance and two adequate ventricles are discussed in this chapter. Furthermore, the management of DORV with transposition of the great arteries is discussed in greater detail in [Chapter 126](#). Two definitions, not mutually exclusive and best used concurrently, are as follows^{17,20}: The 50% rule states that a heart is termed DORV if, in addition to the PA, more than 50% of the aorta (or the PA, in DORV with transposition) arises from the right ventricle. The other definition is that a double conus (subaortic and subpulmonary conal tube, also called infundibulum) is present. This means that there should be no aorta-to-mitral valve continuity.

Classification of DORV by VSD Location and Other Anatomic Determinants of Physiology

DORV is virtually always associated with a VSD. The physiology of DORV encompasses a spectrum that extends from a tetralogy type of DORV to a transposition type of DORV ([Fig. 117-10](#)). The classic pathologic classification of DORV centers on the location of the VSD²⁰ ([Fig. 117-11](#)) and differentiates between subaortic,

FIGURE 117-10 ■ The spectrum of conus development between the tetralogy and transposition ends of the double-outlet right ventricle (DORV). **A**, Tetralogy of Fallot. There is a subpulmonary conus with fibrous continuity between the aortic and mitral valve. **B**, The middle of the DORV spectrum. There are both subpulmonary and subaortic conus. **C**, Transposition of the great arteries. There is a subaortic conus with fibrous continuity between the pulmonary and mitral valves. In all diaphragms, the aortic valve is indicated by the coronary ostia, the tricuspid valve by three leaflets, and the mitral valve by two leaflets; *hatching* indicates conal myocardium. AV, Aortic valve; MV, mitral valve; TV, tricuspid valve. (Modified from Castaneda AR, Jonas RA, Mayer JE Jr, et al: Double outlet right ventricle. In Castaneda AR, Jonas RA, Mayer JE Jr, et al, editors: *Cardiac surgery of the neonate and infant*, Philadelphia, 1994, WB Saunders, pp 445–449.)

FIGURE 117-11 ■ **A**, Double-outlet right ventricle (DORV) with a subaortic ventricular septal defect (VSD). Flow from the left ventricle preferentially enters the aorta. This is similar to what occurs in tetralogy of Fallot. **B**, DORV with a subpulmonary VSD. Left ventricular blood preferentially enters the pulmonary artery, resulting in physiology similar to that seen in transposition of the great arteries. (Modified from Castaneda AR, Jonas RA, Mayer JE Jr, et al: Double outlet right ventricle. In Castaneda AR, Jonas RA, Mayer JE Jr, et al, editors: *Cardiac surgery of the neonate and infant*, Philadelphia, 1994, WB Saunders, pp 445–449.)

subpulmonic, doubly committed, and noncommitted types of VSD. VSD location alone, although important, neither defines the physiology nor is enough information on which to base a decision of the optimal method of repair. The presence or absence of right ventricular outflow tract obstruction is critical to the physiology and clinical presentation (Table 117-1). Furthermore, the great artery relationship, the distance between the pulmonary and tricuspid valves, the prominence of the conal

septum, and the coronary artery anatomy are all important factors that help determine what type of repair should be performed.²¹

DORV with subaortic VSD (see Fig. 117-11) is the most common type of DORV, comprising approximately 50% of all patients with DORV.²¹ With right ventricular outflow tract obstruction, the presentation is similar to tetralogy of Fallot, where a subaortic anterior malalignment VSD is also present. However, tetralogy of Fallot

TABLE 117-1 Pathophysiology of Double-Outlet Right Ventricle

Location of VSD	Right Ventricular Outflow Tract Obstruction	Clinical Presentation

Doubly or noncommitted	Absent	VSD
Doubly or noncommitted	Present	TOF

TGA, Transposition of the great arteries; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

patients will not have a subaortic conus. The presentation and physiology without pulmonary stenosis is similar to that of a child with a large VSD.

DORV with subpulmonary VSD (see Fig. 117-11) is the second most common type of DORV, occurring in 30% of patients.²¹ Because of the location of the VSD, oxygenated left ventricular blood preferentially streams through the VSD into the pulmonary artery while desaturated right ventricular blood streams into the aorta, thereby resulting in a transposition type of physiology. Association with subaortic stenosis, aortic coarctation, or interrupted aortic arch is common. The term *Taussig-Bing heart* is usually applied for hearts with subaortic and subpulmonary coni, side-by-side great arteries, and a subpulmonary VSD.²¹

The doubly committed VSD is immediately beneath both the PA and the aorta. The conal septum is absent or hypoplastic. Clinical presentation is usually similar to that of a subaortic VSD with or without pulmonary stenosis.

The noncommitted VSD type includes any VSD that is located below the conal septum or the junction of conal and muscular interventricular septa. These VSDs are likely to be so remote from the semilunar valves that it is very difficult to create a baffle that directs left ventricular blood flow into the aortic valve. These VSDs are frequently located in the inlet septum (AV canal type), or they can be mid-muscular or apical. Clinical presentation is similar to that of DORV with subaortic VSD and depends on the presence or absence of pulmonary stenosis.²²

Other Important Anatomic Features and Impact on the Type of Repair

Distance between Tricuspid and Pulmonary Valve

The judgment as to which type of repair is best in a specific anatomic situation constitutes the fundamental complexity of the surgical management of DORV. An

intraventricular repair denotes a baffle that is entirely in the right ventricle. The baffle is constructed around the VSD and creates a pathway from the left ventricle to the aorta. The right ventricular outflow thus curves around the left ventricular baffle. When the aorta is pushed away from the left ventricle by a very prominent subaortic conus or if the VSD is remote, a longer tunnel must be created. This often results in D-malposition of the aorta, where the aortic valve moves superior and anterior to the tricuspid valve, allowing the pulmonary valve to move closer to the tricuspid valve. Because the baffle must pass between the tricuspid and pulmonary valves, there is a point when this is no longer possible without either creating baffle obstruction (subaortic stenosis) or occluding the pulmonary valve, thus creating the need for a right ventricle-to-PA conduit. Thus, when planning an intraventricular repair, the distance between the tricuspid valve and the pulmonary valve must be carefully studied on multiple views obtained with echocardiography and angiography (ventriculogram).

Conal Septum

A prominent conal septum also may be in the way of a successful intraventricular baffle. The length of the conal septum is determined by the development of the subaortic and subpulmonary coni. The conal septum may be resected if there are no important AV valve chordae attached to it (Fig. 117-12). A long conal septum may be associated with a closer proximity between the tricuspid valve and the pulmonary valve. It also may be a substrate for the development of future subaortic stenosis, which in turn can be associated with aortic arch hypoplasia.²³

Pulmonary Outflow Tract Obstruction

The presence of pulmonary outflow tract obstruction also needs to be carefully managed during surgery. Intraventricular repair must include relief of any subpulmonary stenosis, usually by means of division of hypertrophied muscle bands and placement of an infundibular outflow patch. Even in mild forms of subpulmonary stenosis, an infundibular patch may be needed because, by definition, an intraventricular baffle protrudes to some extent into the right ventricular outflow tract, thus crowding the right ventricular outflow. An infundibular patch thus prevents the creation of iatrogenic subpulmonary stenosis. Pulmonary stenosis is dealt with as it is during tetralogy surgery, by transannular patch or by valvuloplasty. A Rastelli type of repair is sometimes required when the space between the tricuspid valve and the pulmonary annulus is not sufficient and there is significant pulmonary annular hypoplasia. It is best to then incorporate the entire pulmonary annulus into the baffle, thus creating a generous subaortic passage; divide the main PA; and place a conduit (usually a homograft) between the right ventricle and distal main PA. If the pulmonary annulus is of normal size but an intraventricular baffle is not possible for the reasons cited previously, an arterial switch operation with baffling of the VSD to the pulmonary valve should be performed.²⁴

FIGURE 117-12 ■ **A**, Prominent conal septum can project into the intraventricular baffle pathway. **B**, Resection of the conal septum may be necessary to prevent subaortic stenosis. **C**, Completion of intraventricular repair with a baffle. (Modified from Castaneda AR, Jonas RA, Mayer JE Jr, et al: Double outlet right ventricle. In Castaneda AR, Jonas RA, Mayer JE Jr, et al, editors: *Cardiac surgery of the neonate and infant*, Philadelphia, 1994, WB Saunders, pp 445–449.)

Coronary Artery Anatomy

Knowledge of the coronary artery anatomy is also critical to successful management of DORV, because a left anterior descending coronary artery passing anterior to the right ventricular outflow in the tetralogy end of the spectrum excludes an intraventricular repair and requires a conduit. Complex coronary artery anatomy, frequently seen in Taussig-Bing hearts, renders an arterial switch operation more challenging.

Great Artery Relationship

Most hearts with DORV have normally related great arteries spiraling around each other, with the aorta posterior and to the right of the pulmonary artery. The VSD is usually subaortic. When the great arteries are parallel to each other without a spiral, the aorta can be found side by side with and rightward of the pulmonary artery (D-malposition), anterior to the PA, or side by side and

leftward (L-malposition). The VSD is usually subpulmonary, but it can also be noncommitted.²⁵ Great artery relationship gives an indication of VSD location, but the two can also be independent of one another.²¹

Preoperative Evaluation

The age of the patient and the patient's symptoms are mostly determined by the degree of pulmonary stenosis. Most cases are diagnosed during the neonatal period. Echocardiography is the test of choice for neonates and young infants and is usually sufficient. At the transposition end of the spectrum, a balloon atrial septostomy may be needed to improve mixing. Catheterization also may be necessary in older children to exclude pulmonary vascular disease. To plan (or exclude) a potential intraventricular baffle, a left ventricular injection is helpful so that the dye can be followed as it is ejected by the left ventricle (preferentially into the aorta or pulmonary artery). Important echocardiographic details include the annular sizes of all

FIGURE 117-13 ■ The long synthetic baffle used to direct left ventricular blood to the aorta is best constructed from a partial tube graft. **A**, The suture line is indicated by a dotted line. **B**, Tailoring of the baffle from a tube graft. **C**, A continuous suture technique may be necessary for a very long baffle. **D**, Completion of intraventricular baffle repair of tetralogy of Fallot type of double-outlet right ventricle. (Modified from Castaneda AR, Jonas RA, Mayer JE Jr, et al: Double outlet right ventricle. In Castaneda AR, Jonas RA, Mayer JE Jr, et al, editors: *Cardiac surgery of the neonate and infant*, Philadelphia, 1994, WB Saunders, pp 445–449.)

valves; the size of the left and right ventricles; the relative positions of the great arteries to one another; the degree of development of the conal septum; the chordal attachment to the conal septum; the level and degree of subpulmonary or pulmonary stenosis; the position of the VSD; and the status of the remainder of the septum, the coronary artery anatomy, and the aortic arch anatomy.

Surgical Management

Management of DORV is always surgical. Medical management may be indicated in relatively asymptomatic neonates with tetralogy-type physiology until they are a few months old. Because of markedly improved results with neonatal repairs, surgical palliation in the form of pulmonary artery banding in VSD-type physiology or aortopulmonary shunting in tetralogy-type physiology is

rarely performed. Routine cardiopulmonary bypass with bicaval cannulation is usually used.

Intraventricular Repair of DORV with Subaortic VSD or Doubly Committed VSD without Pulmonary Stenosis

Patients without pulmonary stenosis can generally be managed by placement of a patch baffle around the VSD, thus connecting the left ventricle to the aorta. The relationship of the aortic valve annulus to the VSD rims and to the conal septum must be carefully studied. If there appears to be a need for a larger subaortic circumference, a portion of a synthetic tube graft can be used rather than a flat patch, thus giving the baffle more of a tunnel appearance (Fig. 117-13).¹⁷ If the VSD appears restrictive, it should be enlarged by making an incision

anterosuperiorly, by resecting a wedge of the conal septum, or by doing both.

Intraventricular Repair of DORV with Subaortic VSD or Doubly Committed VSD with Pulmonary Stenosis

Techniques of repair are generally similar to those described for repair of tetralogy of Fallot. However, the VSD is closed by creation of a tunnel rather than a straight patch. Performing an infundibulotomy is generally recommended because subpulmonary stenosis is almost always present. The site of the infundibulotomy has to be carefully planned, staying away from any major coronary arteries. In case of an anomalous coronary artery crossing the right ventricular outflow tract, a conduit is sometimes necessary. Division of parietal and septal bands is always performed, along with placement of an infundibular outflow patch. Stenoses at the level of the pulmonary annulus, pulmonary valve, or branch pulmonary arteries can be handled as in tetralogy of Fallot (see [Chapter 119](#)).

Repair of DORV with Noncommitted VSD

The VSD is generally of the inlet type. Intraventricular (and thus biventricular) repair is difficult, but it can sometimes be accomplished by creating a tunnel from the left ventricle to the aorta. Anatomic variations generally considered to contraindicate a biventricular repair are multiple muscular VSDs, straddling AV valve tissue, or an inability to reliably channel the remote VSD to the aorta. If it is easier to baffle left ventricular blood to the pulmonary valve, or if the pulmonary valve is in the pathway of the baffle and there is no pulmonary stenosis, consideration should be given to performing an arterial switch procedure along with the intraventricular repair.²⁴ It is virtually always necessary to enlarge the VSD superoanteriorly. If the tunnel obstructs the right ventricular outflow tract, an infundibular patch or transannular patch should be placed. If there are significant tricuspid valve attachments to the anterior and superior edge of the VSD, or if a straddling tricuspid or mitral valve is present, attempting an intraventricular repair is generally contraindicated. However, there have been reports of successful division and reimplantation of the tricuspid chordae on the patch.

In the long term, the problem of subaortic stenosis with these complex baffles is real. A double-patch technique has been described that may mitigate this problem.²⁶ A noncommitted muscular trabecular defect can also sometimes be enlarged anteriorly and inferiorly, because the conduction system courses on the superior-posterior aspect of the defect. However, these baffles are often bulky, do not grow with the child, and are generally not very satisfactory. With the improving medium-term outcome for the single-ventricle approach in recent years, it is generally preferable to perform a straightforward single-ventricle repair with preservation of excellent ventricular function rather than a less-than-satisfactory higher-risk biventricular repair, after which multiple and usually complex reoperations will be necessary.²¹ This

approach might also be extended to patients who are at increased operative risk with a conventional biventricular repair.

Repair of DORV with Subpulmonary VSD

At the transposition end of the DORV spectrum, an arterial switch operation is usually preferred. A Taussig-Bing type of DORV can be repaired by an arterial switch operation (the most commonly used type of repair), a Rastelli procedure with Damus-Kaye-Stansel anastomosis, a Nikaidoh procedure, or a REV (réparation à l'étage ventriculaire) procedure. Surgical management of DORV transposition of the great arteries is discussed in [Chapter 126](#).

Results of Surgical Treatment

The early mortality rate is low among patients with non-complex forms of DORV, but it is higher in patients with complicating anatomic features.²⁷ Most complications are mechanical and should be routinely sought with the use of TEE before the patient leaves the operating room. As with VSD surgery, complete heart block and residual VSDs can occur. Inadequate enlargement of VSD or poor baffle configuration can result in subaortic obstruction. Direct measurements in the operating room can help elucidate cases in which TEE is not definitive. Residual muscular obstruction can often be resected through the aortic valve, and an aortotomy is generally a good first approach when approaching this problem. A separate patch also can be placed inside the original patch if it is too narrowing or if there is a waist created by a tortuous course. In cases of DORV with noncommitted VSD, it sometimes may be necessary to convert an acutely failed biventricular repair to a single-ventricle strategy. Significant right ventricular outflow tract obstruction can occur and should be managed as for tetralogy of Fallot. Patients with preoperative pulmonary hypertension are usually better served with implantation of a pulmonary valve. Because of the prolonged myocardial ischemic times needed for these complex repairs, myocardial protection should be carefully attended to; myocardial dysfunction can be a significant problem. Delayed sternal closure and mechanical assistance are important fallback measures that can be lifesaving.

Decompression of the Right Ventricle in the Presence of Right Ventricle to Coronary Connections

Indications for Transplantation

Pulmonary atresia with intact ventricular septum (PA/IVS) is a rare congenital heart defect occurring at a rate of 4 to 10 per 100,000 live births.^{1,2} This malformation is characterized by a variably sized right ventricle that has no exit, failing to provide pulmonary blood flow and unable to decompress itself through the interventricular septum. Blood flow through the ductus arteriosus permits survival at birth, but within hours hypoxemia progresses to death as the ductus closes. Thus, without early diagnosis and treatment, PA/IVS is uniformly fatal. Before 1970, reported survival to 3 years of age was less than 3%.³ By the early 1990s, improvements in diagnosis and management resulted in a 3-year survival rate greater than 60%.⁴ More recent reports indicate that careful initial evaluation and selective management of these patients can achieve survival rates in excess of 90%.⁵

Because this anomaly is rare and its morphology is heterogeneous, most reports and recommendations have been derived from small series with variable morphologic compositions. Although a great deal has been learned from the experiences of individual centers,⁶⁻⁹ much more has been learned from a prospective multi-institutional study initiated by the Congenital Heart Surgeons Society in 1987^{4,10,11} and from more recent, population-based studies from the United Kingdom and Ireland^{1,12} and from Sweden.² Data acquired from these studies have provided important new insights into the spectrum of morphology and about outcomes of surgical treatment of this malformation.

PA/IVS has been described by other monikers in the past, including pulmonary atresia with normal aortic root

and hypoplasia of the right heart. The first description of pulmonary atresia with an intact ventricular septum was in 1784 by Hunter.¹³ Connections between the right ventricle and the coronary arteries were described by Grant in 1926 after examining the heart of a 14-month-old girl.¹⁴ Lauer and colleagues in 1964 were the first to angiographically demonstrate intramyocardial sinuoids.¹⁵ Freedom and colleagues postulated in 1974 that the connections between the right ventricle and the coronary arteries could possibly be related to myocardial ischemia.¹³ The first successful surgical repair of a patient with PA/IVS involved a transventricular valvotomy and was reported by Weinberg and associates in 1962.¹⁵

ANATOMY

Characteristically, PA/IVS occurs in hearts with situs solitus and atrioventricular and ventriculoarterial concordance. The aortic arch is usually left-sided, and a left-sided ductus arteriosus is typical. The essential feature of this lesion is an absent communication between the right ventricle and the pulmonary trunk (Fig. 118-1). The character of the atretic segment ranges from a thin imperforate membrane to a long section of infundibular muscle without a definable lumen. In contrast to pulmonary atresia with ventricular septal defect, in PA/IVS the pulmonary trunk and branch pulmonary arteries are usually near normal in size and configuration. The size and morphology of the right ventricle varies significantly in this condition, and in most patients, the right

ventricular cavity is reduced in size. There is a continuum from tiny “unipartite” chambers that have only an inlet component to larger-than-normal “tripartite” ventricles that have well-defined inlet, trabecular, and infundibular portions. The rare patients with enlarged right ventricular cavities also may have Ebstein anomaly with severe tricuspid regurgitation. More typically, the cavity is small, and marked hypertrophy of the right ventricular wall is present, often contributing to obliteration of the outflow (infundibular) portion of the cavity. The tricuspid valve is usually small with thickened leaflets and abnormal chordae. The diameter of the tricuspid valve correlates

with the size of the right ventricular cavity and provides a useful index of right ventricular size. The right atrium is enlarged, and an interatrial communication, usually a patent foramen ovale, is present. At birth, the ductus arteriosus is patent, providing the only blood flow to the lungs. Significant aortopulmonary collateral arteries are uncommon.

An important anatomic feature of PA/IVS is the presence in some patients of connections between the right ventricle and the coronary circulation (Figs. 118-2 and 118-3). Sinusoids or “intermuscular spaces” in the right ventricular myocardium occur in approximately 50% of patients.⁴ In 90% of these patients, the sinusoids communicate with the coronary arteries. The smaller the tricuspid valve (and thus the right ventricular cavity) is, the more likely it is that right ventricle–coronary arterial fistulas are present. In 15% of patients with these fistulas, significant proximal coronary artery stenoses exist, making myocardial blood flow dependent on blood from the right ventricle (see Table 118-2).¹⁰ Knowledge of the presence of right ventricle–dependent coronary circulation (RVDCC) is important in deciding on surgical therapy, because in these cases, decompression of the right ventricle may cause myocardial ischemia or infarction.¹⁶

FIGURE 118-1 ■ Schematic representation of blood flow in patients with pulmonary atresia with intact ventricular septum. An obligatory right-to-left shunt occurs at the atrial level. Peripheral oxygenation depends on flow through the ductus arteriosus. (Black arrows, deoxygenated blood; white arrows, oxygenated blood; dashed arrows, mixed blood; larger arrows, larger amount of blood flow.) LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

PATHOPHYSIOLOGY

In PA/IVS, desaturated systemic venous blood is obliged to cross the interatrial septum to mix with saturated pulmonary venous blood in the left atrium (see Fig. 118-1). The resultant admixture is ejected into the systemic arterial circulation, and the systemic arterial saturation depends on adequate pulmonary blood flow. Closure of the ductus arteriosus soon after birth markedly reduces pulmonary blood flow, and progressive hypoxemia and tissue acidosis leads to death. Expedient administration of prostaglandin E₁ can temporarily reverse ductal closure

FIGURE 118-2 ■ Right ventricle-to-coronary artery fistulas in pulmonary atresia with intact ventricular septum. **A**, Without coronary stenosis: potential right ventricular steal phenomenon. **B**, With proximal or distal coronary stenosis: potential steal or ischemia. **C**, With coronary occlusion or atresia: potential isolation and myocardial infarction. until a surgical procedure to increase pulmonary blood flow can be performed.

INITIAL CLINICAL PRESENTATION AND MANAGEMENT

Infants with PA/IVS are typically full-term, well-developed infants without other anomalies. Delivery is usually uncomplicated, but cyanosis develops on the first day of life and rapidly progresses to respiratory distress and metabolic acidosis. A murmur is unusual unless significant tricuspid regurgitation exists. There is no splitting of the second heart sound. Chest radiography demonstrates clear lung fields with decreased vascular markings. The electrocardiogram is often normal, although the typical neonatal pattern of right ventricular hypertrophy may be absent. Definitive diagnosis is made using two-dimensional echocardiography, which reveals the right ventricular outflow obstruction and the size of the right ventricle and tricuspid valve and, combined with color flow Doppler techniques, can identify right ventricle–coronary artery fistulas.^{17,18}

As soon as the diagnosis of PA/IVS is suspected, an infusion of prostaglandin E₁ is begun. Elective intubation and controlled ventilation may be advisable, especially if the infant is to be transported to a tertiary treatment center, because apnea is a common complication of prostaglandin E₁ infusion. Cardiac catheterization and cine-angiography are recommended for most of these patients, especially for those with moderate or severe right ventricular hypoplasia. Right ventriculography, aortography, and, when indicated, selective coronary angiography are performed to determine the presence and extent of right ventricle–to–coronary artery fistulas and the presence of coronary artery obstructions (see Figs. 118-2 and

118-3).^{16,19} At catheterization, an adequate atrial communication must be ensured. If echocardiography and catheterization indicate that right ventricle–to–pulmonary artery decompression cannot be performed and a flow gradient exists between the right and left atrium, a balloon atrial septostomy is performed at this catheterization.

SURGICAL MANAGEMENT

The ideal long-term outcome for all infants with PA/IVS would be to achieve a two-ventricle circulation with the right ventricle providing all blood flow to the lungs at a low filling pressure without residual right-to-left shunt. The anatomic heterogeneity of this group of patients, however, prevents the achievement of this goal in all patients. In fact, this ideal is achieved in only one third of patients surviving infancy (see Fig. 118-10).¹⁰ A more realistic outcome for the remaining patients is the elimination of cyanosis by separating the systemic and pulmonary circulations without limiting cardiac output or inducing excessively elevated systemic venous pressures. Such an outcome can be achieved with a one-ventricle repair (the Fontan operation) for hearts whose right ventricle cannot contribute to pulmonary blood flow, or with a one-and-one-half-ventricle repair for hearts whose right ventricle can provide a portion of pulmonary blood flow. Careful assessment of right ventricular size and coronary artery anatomy is crucial to selecting the appropriate strategy for each patient.

In neonates, it is useful to classify right ventricular hypoplasia into mild, moderate, and severe degrees (Table 118-1). Echocardiographic measurement of the diameter of the tricuspid valve with conversion to a z-value provides a quantitative measurement to facilitate classification.²⁰ A website (www.parameterz.com) is available for rapid and easy determination of z-scores. Patients with mild right ventricular hypoplasia have tricuspid valve z-values of –2 or greater. Tricuspid z-values between –4 and –2 indicate moderate right ventricular hypoplasia, and z-values of –4 or less are seen in patients with severe right ventricular hypoplasia. Tripartite right ventricles with a well-developed right ventricular outflow tract fall into the mild group, whereas unipartite right ventricles without a definable infundibular or trabecular portion are classified as severe.²¹ Patients with mild right ventricular hypoplasia have definite potential for conversion to a two-ventricle system at the time of definitive repair, whereas those with severe right ventricular hypoplasia can achieve only separation of systemic and pulmonary circulations with a one-ventricle repair (a Fontan operation). Patients with moderate right ventricular hypoplasia are also potential candidates for two-ventricle or one-and-one-half-ventricle repair, provided they do not have RVDCC.

Initial Palliation

The surgical management of PA/IVS is typically undertaken in two or more stages, the first for palliation and subsequent procedures directed at definitive repair. To

TABLE 118-1 Effect of Degree of Right Ventricular Hypoplasia on Management of Pulmonary Atresia with Intact Ventricular Septum

Parameter/ Management	Degree of Right Ventricular Hypoplasia		
	Mild	Moderate	Severe
Tricuspid z-value	>−2	−2 to −4	<−4
Right ventricular morphology	Tripartite	Bipartite	Unipartite
Infundibular cavity	Present	Intermediate	Absent
Right ventricle–dependent coronary circulation	Rare	Possible	Common
Initial palliation	Transannular patch ± shunt. Consider transcatheter valvotomy or hybrid procedure	Transannular patch + shunt. Consider hybrid procedure (no right ventricular decompression if right ventricle–dependent coronary circulation)	Shunt only
Definitive operation	Two-ventricle repair	Two-ventricle repair; one-and-one-half-ventricle repair; Fontan if right ventricle–dependent coronary circulation	Fontan

FIGURE 118-4 ■ Open pulmonary valvotomy without cardiopulmonary bypass can be performed via a median sternotomy or a left thoracotomy. **A**, After clamping the pulmonary trunk just proximal to the bifurcation, the pulmonary artery is opened and the atretic pulmonary valve is opened sharply. **B**, A Fogarty catheter positioned in the infundibulum provides hemostasis as the atretic valve is excised. (Modified from Kanter KR, Pennington DG, Nouri S, et al: Concomitant valvotomy and subclavian-main pulmonary artery shunt in neonates with pulmonary atresia and intact ventricular septum. *Ann Thorac Surg* 43:490–494, 1987.)

ensure early survival, pulmonary blood flow must be maintained after ductal closure. Although the creation of a systemic-to-pulmonary shunt can ensure continued pulmonary blood flow, the right ventricle must be assessed for its potential recruitment into the circulation. When possible, decompressing the right ventricle into the pulmonary artery permits right ventricular growth such that a two-ventricle repair may become feasible. Failure to decompress the right ventricle at initial palliation essentially eliminates the possibility of ever achieving a definitive two-ventricle repair.²²

Thus, neonates with mild to moderate right ventricular hypoplasia are best served by relieving the right ventricle-to-pulmonary artery obstruction. This may be accomplished with or without cardiopulmonary bypass. Without bypass, a pulmonary valvotomy can be performed blindly, with a transventricular dilator,²³ or under direct vision through the main pulmonary artery (Fig.

118-4).²⁴ Interventional catheter and hybrid techniques are now being applied at some centers for this purpose (see [Trends and Controversies](#), later). The use of cardiopulmonary bypass allows more controlled access into the right ventricular outflow tract so that obstructing infundibular muscle can be excised under direct vision and a transannular outflow patch can be placed (Fig. 118-5). By maximizing unobstructed forward flow, transannular patching provides the greatest possibility for right ventricular growth.^{4,25} Because early postoperative right ventricular failure may cause increased right-to-left shunting across the patent foramen ovale, and antegrade flow from the right ventricle may be limited, a systemic-to-pulmonary artery shunt (a 3- or 3.5-mm polytetrafluoroethylene [PTFE] tube graft) also should be placed to prevent life-threatening hypoxia. Initial results from the Congenital Heart Surgeons Society's study suggest that concomitant insertion of a transannular patch and placement of a systemic-to-pulmonary artery shunt is the optimal initial treatment for neonates with tricuspid valve z-values between −1.5 and −4 (Fig. 118-6).⁴ In that study, when a valvotomy or transannular patch was performed without a concomitant systemic-to-pulmonary artery shunt, approximately 50% of the patients required shunt placement within the first 4 weeks after the initial procedure. In addition, approximately 40% of patients treated initially with pulmonary valvotomy required a transannular patch at a subsequent operation.⁴ On the other hand, any form of right ventricular decompression is contraindicated if RVDCC exists.

Neonates with severe right ventricular hypoplasia or RVDCC (or both) are best placed on a definitive one-ventricle (Fontan) pathway. Thus, initial surgical therapy should be limited to a systemic-to-pulmonary artery shunt (see Fig. 118-6).⁴ A 3.5-mm PTFE tube graft placed via a median sternotomy or a right thoracotomy from the innominate or right subclavian artery to the right pulmonary artery provides adequate pulmonary blood flow and facilitates shunt access at the time of definitive one-ventricle repair. Shunts greater than 4 mm should be avoided because they may result in excessive pulmonary blood flow and low diastolic arterial blood pressure, causing life-threatening myocardial ischemia.

FIGURE 118-5 ■ Placement of a transannular patch and a systemic-to-pulmonary artery shunt. A 3- or 3.5-mm polytetrafluoroethylene (PTFE) tube graft is placed from the innominate artery to the right pulmonary artery. Cardiopulmonary bypass is established and the shunt and ductus are temporarily occluded. A pulmonary artery incision is extended into the right ventricular outflow tract. Obstructing tissue is excised, and a pericardial patch is sewn in place. Separation from bypass is done with the shunt open and the ductus occluded. If peripheral oxygen saturations exceed 80%, the ductus is ligated. If peripheral oxygen saturations are less than 80%, the ductus is unsnared as demonstrated at right. (Black arrows, deoxygenated blood; white arrows, oxygenated blood; dashed arrows, mixed blood).

FIGURE 118-6 ■ The effect of tricuspid valve diameter (z-value) and type of initial procedure on 6-month survival in neonates with pulmonary atresia and intact septum. This nomogram was derived after analyzing 171 neonates and solving a multivariable equation setting birth weight (BW) at "3.1 kg," right ventricle (RV)-dependent circulation at "no," and date of shunt operation at "1991." RV outflow procedure includes valvotomy and transannular patch. (Modified from Hanley FL, Sade RM, Blackstone EH, et al: Outcomes in neonatal pulmonary atresia with intact ventricular septum. A multiinstitutional study. *J Thorac Cardiovasc Surg* 105:406-423, 1993.)

Definitive Procedures

Two-Ventricle Repair

Patients selected at initial palliation for a two-ventricle strategy should have echocardiographic evidence of satisfactory right ventricular decompression with estimated right ventricular pressure less than or equal to one half of systemic arterial pressure. Those infants treated originally with valvotomy rather than transannular patching are especially vulnerable to residual or recurrent right ventricular outflow tract obstruction,^{4,22} which should be relieved by a second right ventricular outflow tract procedure (a transannular patch) before considering conversion to a two-ventricle circulation. Follow-up cardiac catheterization should be performed between 6 and 12 months of age. At catheterization, the systemic-to-pulmonary artery shunt is temporarily occluded. If arterial saturations remain high, the atrial septal defect (patent foramen ovale) is occluded as well. If right atrial pressure remains below 15 mm Hg and cardiac output is adequate, the shunt and atrial communication can be closed permanently and a two-ventricle circulation achieved. At some centers, the shunt and atrial defect can be closed during the catheterization using percutaneous techniques.^{26,27}

One-and-One-Half Ventricle Repair

Patients studied at 6 to 12 months who do not tolerate temporary occlusion of the systemic-to-pulmonary artery shunt are receiving too little pulmonary blood flow from the right ventricle to achieve success from a two-ventricle repair. Assuming there is no significant residual right ventricular outflow obstruction, these patients should be considered candidates for a one-and-one-half-ventricle repair. This repair involves takedown of the arterial systemic-to-pulmonary shunt and the creation of a bidirectional superior cavopulmonary anastomosis (a bidirectional Glenn procedure), which relieves the right ventricle of the superior vena caval blood flow. Ideally, the atrial septal communication is closed at the same operation. However, if the right atrial pressure exceeds 15 mm Hg, a small (4-mm) fenestration can be left. Catheter closure of the fenestration can usually be performed within months of the surgical procedure.²⁷

Alternatively, a purse-string suture and an adjustable snare can permit incremental closure of the atrial septal defect in the postoperative period (Fig. 118-7).²⁸ Patients with tricuspid z-values as small as -6 may be definitively managed with the one-and-one-half-ventricle strategy.²⁹

One-Ventricle Repair

Infants with severe right ventricular hypoplasia or RVDCC (or both) are typically designated for a one-ventricle strategy at initial palliation. At 4 to 6 months of age, these patients undergo takedown of the systemic-to-pulmonary shunt and the creation of a bidirectional cavopulmonary anastomosis. At 2 to 4 years of age, they are considered candidates for the Fontan operation. Before the Fontan operation, cardiac catheterization is essential to ensure adequate left ventricular function and low pulmonary vascular resistance. Poor left ventricular function would leave cardiac transplantation as the only alternative therapy. Heart-lung transplantation is the only alternative if pulmonary vascular resistance is elevated. Fortunately, the early creation of a bidirectional cavopulmonary anastomosis appears to help preserve ventricular function and prevent the development of pulmonary vascular disease so that those drastic measures are rarely necessary. When performing the bidirectional Glenn procedure on cardiopulmonary bypass in patients with RVDCC, the surgeon must avoid low right ventricular preload to avoid poor coronary perfusion. The right ventricle should remain filled and ejecting, because myocardial perfusion occurs only during systole. Patients with RVDCC who sustain cardiac arrest may not respond well to resuscitation with extracorporeal membrane oxygenation (ECMO). ECMO will empty the right heart and significantly hinder coronary perfusion.³⁰ After the superior cavopulmonary anastomosis, the saturations in the right ventricular cavity are significantly increased, and this is likely beneficial for patients with RVDCC.³¹

When the Fontan procedure is performed, inferior vena caval blood flow is directed to the pulmonary arteries. This can be performed with a lateral atrial tunnel technique, wherein a baffle of PTFE is placed inside the right atrium (Fig. 118-8),³² or with an extracardiac conduit.³³ Many surgeons prefer to place a small fenestration in the baffle to permit some right-to-left shunting

FIGURE 118-7 ■ Creation of a one-and-one-half-ventricle circulation. **A**, Small right ventricle unable to support two-ventricle repair. **B**, Superior vena caval flow is directed to the right pulmonary artery with a bidirectional cavopulmonary anastomosis. Residual right ventricular outflow tract stenosis is relieved with a transannular patch. Placement of an adjustable snare around the atrial septal defect permits incremental closure in the postoperative period. (Modified from Billingsley AM, Laks H, Boyce SW, et al: Definitive repair in patients with pulmonary atresia and intact ventricular septum. *J Thorac Cardiovasc Surg* 97:746-754, 1989.)

to maintain cardiac output in the perioperative period, when pulmonary vascular resistance may be elevated.³⁴ Routine fenestration, however, may not be necessary when an extracardiac conduit is used.³⁵ It also may be preferable to avoid fenestration when RVDCC is present. Enlarging the atrial septal defect and unroofing the coronary sinus to ensure that the blood entering the right ventricle is well oxygenated has also been recommended for RVDCC (see Fig. 118-8).

RESULTS

Early and Midterm Outcomes

The reports from the Congenital Heart Surgeons Society (CHSS) continue to provide the best overall perspective of outcomes in neonates with PA/IVS.^{4,10,11} This prospective multi-institutional study involves 31 institutions and enrolled 408 unselected neonates with this diagnosis within a 10-year period (1987-1997). The initial right ventricular morphology and tricuspid valve size (z-value) were known for all patients, and follow-up through 2002 was 91% complete. Techniques for surgical management were not randomized but left to the discretion of each institution. The overall survival was 60% at 5 years and 58% at 15 years (Fig. 118-9). At 15 years, 33% had undergone a two-ventricle repair, 20% a Fontan repair, and 5% a one-and-one-half-ventricle repair, and 38% died before reaching definitive repair (Fig. 118-10). In this unselected group, 49% of patients were found to have severe right ventricular hypoplasia (z-score ≤ -4), and 36% had moderate right ventricular hypoplasia (z-score -2 or -3) (Table 118-2). Additionally, 6% of the cohort had RVDCC (none with a z-score ≥ -2), and 38% had right ventricle–coronary artery fistulas. Increasing tricuspid valve z-score, larger right ventricle size, higher

birth weight, and a lesser degree of right ventricle–to–coronary artery fistulas were all found to be significant determinants of achieving a two-ventricle repair. Also, tricuspid valve morphology was found to be an important determinant of successful two-ventricle repair, as Ebstein malformation was associated with an increased risk of death. The 2004 CHSS report highlighted the importance of morphology-specific repair.¹⁰ The most favorable outcomes were achieved by institutions that applied the Fontan operation for patients with severe morphology, and a two-ventricle repair for patients with favorable morphology (Fig. 118-11).

The 2005 report from the United Kingdom and Ireland Collaborative Study of Pulmonary Atresia with Intact Ventricular Septum identified three variables as independent predictors of death—these variables are birth weight, right ventricular dilation, and the partite status of the right ventricle.³⁶ Only one third of patients born at less than 2 kg survived, and each additional kilogram of weight was associated with a 44% reduction in the risk of death. Eighty percent of those undergoing operation with a significantly dilated right ventricle died. The 1- and 5-year survival rates for those with a tripartite right ventricle were 78% and 74%, respectively (Fig. 118-12). This is significantly better than the 44% and 22% seen for those with unipartite right ventricle anatomy. At this 9-year follow-up report, 29% had achieved a biventricular repair, 3% a one-and-a-half-ventricle repair, and 10.5% a univentricular repair, and 41% had died.

Using information derived from the CHSS study, Boston Children's Hospital applied a policy of routine coronary angiography, right ventricular decompression with transannular patching for patients without RVDCC, and a systemic-to-pulmonary shunt in virtually all patients. In a consecutive group of 47 patients from 1991 to 1998, this institution achieved an actuarial survival rate

All patients begin alive at the time of initial admission (time = 0) and thereafter migrate to an end state at a time-dependent rate defined by the hazard functions. At any point in time, the sum of the proportion of children in each state is 100%. HTx, Heart transplantation; V, ventricle. (Modified from Ashburn DA, Blackstone EH, Wells WJ, et al; Congenital Heart Surgeons Study members: Determinants of mortality and type of repair in neonates with pulmonary atresia and intact ventricular septum. *J Thorac Cardiovasc Surg* 127[4]:1000–1007, 2004; discussion 1007–1008.)

of 98% at 1 year, 5 years, and 7.5 years.⁵ To achieve this excellent survival rate, a one-ventricle or a one-and-one-half-ventricle repair was required in most patients. On the other hand, in patients with RVDCC, survival is not nearly as good. In another report from the same institution, patients with RVDCC had an overall mortality of almost 19%. Also, patients with aortocoronary atresia had 100% mortality.³⁰ Green Lane Hospital in New

Zealand also had an extremely high mortality rate (91%) among patients with aortocoronary atresia.³⁷

Late Follow-up

The Congenital Heart Surgeons Society recently evaluated surviving patients from its original multi-institutional study to determine if biventricular repair was associated

TABLE 118-2 Morphologic Characteristics in 334 Neonates for Whom an RV Size Score Was Assigned

RV Size	Patients (n)	% of 334	Tricuspid Value Z-Score			RV-CA Fistulas	RVDCC
			Median	Range*	25th Percentile		
-5 (severe hypoplasia)	62	19	-2.3	-5.4 to 4.8	-3.3	35 (56%)	5 (8%)
-4	100	30	-2.3	-5.3 to 0.6	-3.1	55 (55%)	10 (10%)
-3	79	24	-1.1	-5.2 to 5.0	-1.9	28 (35%)	4 (14%)
-2	40	12	-0.3	-3.1 to 3.2	-1.0	5 (13%)	0
-1	22	7	0.4	-2.9 to 2.9	-1.2	3 (14%)	0
0 (normal for age)	16	5	1.5	-1.6 to 5.0	0.6	0	0
≥1 (enlarged)	15	4	2.4	-1.0 to 6.0	0.4	0	0

*High upper limits of tricuspid valve z-score in neonates with a diminutive right ventricle are attributable to associated Ebstein malformation.

CA, Coronary artery; RV, right ventricle; RVDCC, right ventricle-dependent coronary circulation.

FIGURE 118-11 ■ Results at an institution favoring both two-ventricle (2-V) and Fontan pathways. Patients with severe morphologies undergo the Fontan operation, and patients with favorable morphologies undergo two-ventricle repair. The mortality rate is low, and most children have had a definitive repair by 5 years. (Modified from Ashburn DA, Blackstone EH, Wells WJ, et al; Congenital Heart Surgeons Study members: Determinants of mortality and type of repair in neonates with pulmonary atresia and intact ventricular septum. *J Thorac Cardiovasc Surg* 127[4]:1000–1007, 2004; discussion 1007–1008.)

with late (≥ 10 years) benefit in terms of functional health status and exercise capacity relative to a univentricular or one-and-one-half-ventricle repair.¹¹ Of 271 current survivors of the original cohort, 106 participated in the cross-sectional study. In this report, patient-perceived physical functional health status and measured exercise capacity were reduced, regardless of repair pathway. Peak oxygen consumption was low across all groups and was positively correlated with larger initial tricuspid valve z-score. The peak VO_2 in the biventricular repair group with low tricuspid valve z-scores tended to be lower than peak VO_2 in the one-and-one-half-ventricle group with comparable tricuspid valve z-scores. These findings suggest that patients with more severe degrees of right heart hypoplasia who are forced down a biventricular pathway may be at greater risk of late deficits in aerobic capacity.

Another study, from the Mayo Clinic, looked at clinical outcomes in adult survivors with PA/IVS.³⁸ Of 20

Survival	1 Year (CI)	5 Year (CI)
Tripartite	78% (69%-87%)	74% (64%-84%)
Bipartite	67% (53%-80%)	57% (43%-72%)
Unipartite	44% (12%-77%)	22% (0%-49%)

FIGURE 118-12 ■ Survival curve for all patients undergoing operative procedures, grouped by so-called partite status of the right ventricle ($N = 168$). CI, 95% confidence interval. (Modified from Daubeney PE, Wang D, Delany DJ, et al; UK and Ireland Collaborative Study of Pulmonary Atresia with Intact Ventricular Septum: Pulmonary atresia with intact ventricular septum: predictors of early and medium-term outcome in a population-based study. *J Thorac Cardiovasc Surg* 130[4]:1071, 2005.)

patients, 5 died during the 10-year study period at a median age of 32 years. All patients in this cohort required surgical or catheter reinterventions in adulthood, regardless of type of repair, and 80% developed atrial arrhythmias. Thus, despite survival into adulthood, the risk of morbidity and mortality continues for these patients.

TRENDS AND CONTROVERSIES

Transcatheter Pulmonary Valvotomy

Advances in interventional techniques now make it possible for some infants with PA/IVS to undergo antegrade decompression of the right ventricle without surgery, while still in the catheterization laboratory. Using mechanical, laser, or radiofrequency energy at the tip of

a catheter, the membranous atresia can be perforated and the resulting communication dilated with percutaneous balloon technique.³⁹⁻⁴¹ As experience with this procedure increases, it is being considered as first-line treatment in place of surgical intervention at some centers.⁴² Right ventricular growth and a definitive two-ventricle circulation have been achieved with this technique in some patients.^{41,43} Use of this approach, however, requires careful selection of patients and is essentially limited to infants with a patent infundibulum and a right ventricle large enough to support the pulmonary circulation without a systemic-to-pulmonary shunt. This approach may not adequately address the small pulmonary annulus or significant subpulmonary obstruction. Accordingly, after catheter valvotomy, some patients have required prolonged hospitalization for continued administration of prostaglandin E₁ or surgery (or both) to place a systemic-to-pulmonary shunt.⁴⁰

In one recent series, 88% of those undergoing transcatheter pulmonary valvotomy required surgical intervention within 2 weeks of the initial interventional procedure.⁴⁴ In that series, most operations (87%) involved a procedure directed at the right ventricular outflow tract in addition to shunt placement. In another single-institution review, 64% of those initially receiving catheter-based therapy required surgical intervention before discharge.⁴⁵ A more recent report from Boston Children's Hospital confirms a similar rate (62%) of surgery prior to discharge.⁴⁶ In this study all but one patient required a systemic to pulmonary shunt to augment pulmonary blood flow.

Stenting of the arterial duct has become an alternative technique for ensuring adequate pulmonary blood flow in selected patients while right ventricular function is being established. Ductal stenting can be performed within days after catheter-based valvotomy if the infant cannot be weaned from prostaglandin⁴⁷ or concomitantly with the valvotomy.⁴⁸ The risk factors determining the need for an additional source of pulmonary blood flow (shunt or ductal stent) continue to be defined for these patients. As expected, smaller tricuspid valve z-scores correlate with a greater need for adding pulmonary blood flow.^{46,49} In one study 80% of patients with a bipartite right ventricle required an additional source of pulmonary blood flow.⁴⁷ Another case series looked at 143 patients with PA/IVS, 37 of whom had a bipartite right ventricle.⁴⁸ All 37 patients underwent radiofrequency valvotomy and stenting of the ductus as the initial procedure. Forty-eight percent of these patients went on to

achieve a biventricular circulation, and 26% underwent one-and-one-half-ventricle repair. A large multicenter study that examined ductal stenting over an 18-year period reported a 94% success rate in patients with PA/IVS.⁵⁰ The long-term impact of ductal stenting on future operations and pulmonary artery anatomy is not clear. In one study, major late complications of patent ductus arteriosus stenting were not encountered, and the stented patent ductus arteriosus did not pose a major surgical challenge at the time of bidirectional Glenn surgery.⁴⁸

Catheter-based therapy for PA/IVS patients is becoming the preferred approach at most centers when the anatomy is favorable. Moller's analysis of more than 1000 PA/IVS patients from the multi-institutional Pediatric Cardiac Care Consortium from 1982 to 2006 revealed a steady increase in the frequency of balloon pulmonary valvotomy along with a corresponding decrease in surgical pulmonary valvotomy (Table 118-3).⁵¹

Hybrid Procedures

Despite the increasing preference for catheter-based therapy in select neonates with PA/IVS, the percutaneous approach is associated with significant rates of procedural failure and serious complications. Many neonates have required surgical intervention in the neonatal period, either to augment pulmonary blood flow or to repair a complication associated with the percutaneous approach. An alternative hybrid approach integrating a sternotomy with transventricular perforation of the atretic pulmonary membrane and balloon pulmonary valvotomy was first described in 2007.⁵² This approach also allows for radiofrequency perforation of the valve membrane.⁵³ Potential advantages of the hybrid approach include avoidance of neonatal cardiopulmonary bypass, mitigation of the technical failure rate of the percutaneous approach (due to direct access to the right ventricular outflow tract), and a lower complication rate.

A recent study prospectively enrolled 10 neonates with PA/IVS to undergo a hybrid procedure.⁵⁴ All patients had a successful balloon valvotomy, one patient required reopening of the patent ductus arteriosus, and one required a concomitant Blalock-Taussig (BT) shunt. Of note, all patients had a tricuspid valve z-score of -2 to 2, suggesting mild right ventricular hypoplasia. The investigators also reported mild complications in three patients and no mortality. Another single-center report compared patients who underwent surgical right ventricular decompression with a hybrid cohort.⁵⁵ The researchers found

TABLE 118-3 Frequency of Procedures in Neonates with PA/IVS by Time Periods

Time Period	1982-1989	1990-1995	1996-2001	2002-2006
Number of neonates	199	287	298	255
Systemic-pulmonary shunt	170 (85%)	243 (85%)	255 (86%)	206 (81%)
Pulmonary valvotomy	81 (41%)	71 (25%)	57 (19%)	22 (10%)
Balloon pulmonary valvuloplasty	0	15 (5%)	46 (15%)	81 (32%)

PA/IVS, Pulmonary atresia with intact ventricular septum.

Modified from Moller JH: Operative and interventional procedures in 1039 neonates with pulmonary valve atresia and intact ventricular septum. A multi-institutional study. *Prog Pediatr Cardiol* 29:15-18, 2010.

no difference between the surgical and hybrid cohorts in terms of maximum vasoactive-inotropic score, duration of mechanical ventilation, intensive care unit length of stay, or overall hospital length of stay. Overall complication rates were also similar. All surgical patients received a BT shunt, whereas only 71% of the hybrid patients received a BT shunt.

Decompression of the Right Ventricle in the Presence of Right Ventricle to Coronary Connections

Antegrade right ventricular decompression is required to recruit the right ventricle for an ultimate two-ventricle or one-and-one-half-ventricle circulation. When significant communications (fistulas) between the right ventricle and the coronary circulation are present, controversy exists regarding the advisability and technique of right ventricular decompression. Virtually all authors agree that when proximal coronary obstructions are also present that make the coronary circulation dependent on the right ventricle, decompression of the right ventricle is contraindicated. Consensus is not uniform, however, when significant right ventricle-to-coronary circulation connections are present without proximal coronary artery obstructions. Some authors advise against decompression in these cases for fear that decreasing right ventricular pressure will result in a steal phenomenon, with compromised blood flow to portions of myocardium (see Fig. 118-2A).⁵⁶⁻⁵⁸ Other authors express concern that failure to decompress the right ventricle will allow these fistulas to persist, resulting in ischemia and progressive myocardial fibrosis.^{23,59} To encourage regression of these connections, these authors recommend antegrade decompression if an infundibular cavity is present, or retrograde decompression by tricuspid valve excision if there is no infundibulum.²³ Other authors recommend tricuspid valve closure⁶⁰ or right ventricular thromboexclusion⁵⁹ to prevent deoxygenated blood from entering the coronary circulation. It was recently reported that thromboexclusion may increase the left ventricular shortening fraction.⁶¹

In a study of patients with PA/IVS who have right ventricle-to-coronary artery connections and a spectrum of coronary artery abnormalities, Giglia and associates¹⁶ found that antegrade right ventricular decompression could be performed without jeopardizing left ventricular function when coronary stenoses were absent or when stenosis involved only a single coronary artery. At present, therefore, most centers attempt right ventricular decompression in the presence of right ventricle-to-coronary artery connections when RVDCC has been ruled out and antegrade decompression is possible.⁵ When antegrade decompression is not possible, the approach to right ventricular decompression remains controversial and continues to be institution specific.^{5,23,59,60,62}

Indications for Transplantation

Because early mortality continues to occur despite appropriate surgical management,^{1,2} cardiac transplantation has

been considered a suitable therapy for a small subset of patients with PA/IVS.⁶² In the 2004 CHSS report (408 patients), only 2% of patients underwent cardiac transplantation.¹⁰ Among patients with PA/IVS who should be considered for heart transplantation are those with RVDCC and aortocoronary atresia. The few reports of this subset indicate that other methods of treatment have resulted in almost uniform mortality.^{30,37} Also, patients with PA/IVS who have severe tricuspid regurgitation and a massively dilated right ventricle ("wall-to-wall" heart) have an extremely poor prognosis and should be considered for primary heart transplantation.⁶³ The presence of RVDCC alone is not an absolute indication for cardiac transplantation unless there is poor left ventricular function. Some centers, however, have recommended that infants with RVDCC and satisfactory left ventricular function be considered appropriate candidates because of the high early mortality in this group, even when right ventricular decompression is avoided.^{56,64} Such a policy remains controversial, however, because other centers have had satisfactory results using a single-ventricle approach with these patients,^{5,59} including Powell and associates,⁶⁵ who reported a 5-year survival of 83% in these patients. Such survival exceeds the 65% to 70% that is currently being achieved for infant heart transplantation.⁶⁶ Nevertheless, for a specific infant with signs of ischemia or left ventricular dysfunction (or both), transplantation may be the best strategy.

TETRALOGY OF FALLOT WITH ABSENT PULMONARY VALVE

HISTORY

Stensen, in 1672, described for the first time the anatomic features of what is now termed *tetralogy of Fallot* (TOF).¹ In 1888, Etienne-Louis Arthur Fallot published his findings describing the four features of the congenital cardiac anomaly that bears his name²: infundibular pulmonic stenosis, ventricular septal defect (VSD), dextroposition of the aorta, and right ventricular (RV) hypertrophy.

More than 50 years later, the first successful palliative surgical therapy for TOF was performed by Alfred Blalock and Helen Taussig in 1944 at the Johns Hopkins University, following the experience of Vivien Thomas, who in Blalock's laboratory was producing an animal model of pulmonary hypertension by anastomosing end-to-side the subclavian artery to the pulmonary artery in dogs.³ Other operative operations to augment the pulmonary blood flow were soon developed by Potts, Waterston, and others.⁴⁻⁷ The first successful repair of this condition was performed by Lillehei and Varco at the

University of Minnesota in 1954 using "controlled cross circulation," with either father or mother serving as the oxygenator and blood reservoir.^{8,9} Kirklin reported the first repair of TOF using a pump oxygenator at the Mayo Clinic in 1955.^{10,11} Barrett-Boyes and Neutze¹² and Castaneda¹³ opened the avenue of the new era of TOF repair by demonstrating the feasibility and the advantages of one-stage repair compared with a two-stage approach. The literature reveals excellent operative results and a low mortality rate. Nevertheless, the results of repair over decades have shown that chronic pulmonary valve (PV) regurgitation, together with a RV geometries distortion secondary to ventricular patching, leads to chronic RV failure.¹⁴⁻¹⁵ Therefore, one is now focusing on techniques aimed to preserve the long-term RV function.

PREVALENCE

Tetralogy of Fallot is the most common cyanotic congenital heart defect in all age groups, constituting

approximately 8% of all congenital heart defects. It occurs in nearly 0.19 to 0.26 in 1000 live births, with a prevalence of about 3.9 per 10,000 live births in the United States.¹⁶⁻²⁰ Furthermore, TOF is one of the most common congenital heart lesions requiring intervention in the first year of life and occurs equally in males and females.¹⁶⁻¹⁸ Mutations in several human genes have thus far been identified in TOF. The deletion of human *TBX1* appears to be the basis for the 15% of TOF attributable to chromosome 22q11.2 microdeletion, although *TBX1* mutations in nondeleted TOF patients remain to be identified.²¹⁻²³ Other identified mutations included the *NKX2.5*, which accounts for 4% of TOF²⁴ and the mutation *JAG1* in Alagille syndrome in which the incidence of TOF is high.^{25,26} The gene or genes causing TOF in trisomy 21, 18, and 13, which together account for 10% of TOF cases,²⁷ are as yet unidentified. Thus, in approximately 70% of TOF patients, a genetic etiology remains to be determined.

ANATOMY AND PHYSIOLOGY

The original concept of four coexisting defects described by Fallot in 1888, was revisited by Richard Van Praagh in 1970,²⁸ who introduced the concept that TOF is actually a “monology” resulting essentially from the underdevelopment and malalignment of the RV infundibulum or conus. According to Anderson and colleagues,²⁹ however, the right ventricular outflow tract (RVOT) in TOF results from the deviation of the infundibular septum cephalad and anterior. This anomaly of the infundibular septum narrows the RVOT, leading to a subpulmonary obstruction of variable degree, the more severe creating an atretic infundibulum and/or valve. Prominent muscle bands originating from the septal region of the infundibular septum to extend the RV free wall contribute to the RVOT obstruction. Displacement of the infundibular septum away from the anterior and posterior limbs of the trabecula septomarginalis (septomarginalis trabeculation, septal band) results in a typical anterior malalignment VSD. The aortic valve is located directly behind the infundibular septum because of the anterior displacement of this structure; therefore, the aortic valve overrides the ventricular septum by various degrees. In those cases in which the aortic valve remains aligned predominantly to the RV, particularly when a mitral-aortic valve discontinuity (subaortic conus) is present, such a malformation is termed *double outlet right ventricle*, TOF-type.³⁰

The foramen ovale is mostly open in young infants. If left open during correction, it allows decompression of the right ventricle, when failing during the early postoperative period.

Pulmonary Valve and Pulmonary Valve Annulus

The pulmonary valve is stenotic in 75% of cases because of a hypoplasia of the annulus and fusion of leaflets, supravalar tethering, or a combination of these factors.^{29,31,32} Tethering of the leaflets often distorts the

main pulmonary artery at the sinotubular junction, forming a ridge that can be obstructive, producing supravalar stenosis. The leaflets themselves are often thickened and dysplastic with fusion at their commissural attachment, further reducing the effective annulus size. The pulmonary valve annulus is invariably smaller than the aorta (the opposite of normal); however, it is not necessarily significantly obstructive.

A recent unpublished combined study of the University of Padua, Italy, and the Cardiac Registry at the Children’s Hospital, Boston, have analyzed 101 heart specimens (67 belonging to Children’s Hospital in Boston and 34 to the University of Padua) with TOF, focusing specially on the PV anatomic features. The PV proved to be predominantly bicuspid in 65 specimens (65%), less frequently tricuspid ($n = 23$ [23%]) and rarely unicuspid ($n = 12$ [12%]) and quadricuspid in 1 case (1%). In 53 specimens (53%) of all cases, the PV cusps were normal. This is an important finding, in view of recent new surgical techniques aimed at preserving the native PV during repair (Figs. 119-1 and 119-2).

Ventricular Septal Defect

The VSD is typically large and subaortic, and it reflects in its very nature the deviation of the infundibular septum.²⁹ The VSD is located between the deviated infundibular septum (conus) and the two limbs of the trabecula septomarginalis (septal band). Its posterosuperior margin is limited by the ventriculo-infundibular fold and the aortic valve (which is visible by the surgeon during repair), superiorly by the infundibular septum, anteriorly by the anterosuperior limb, and inferiorly by the posteroinferior limb of the septal band and the muscular septum (Figs. 119-3 through 119-6). In 20% of cases, there is a well-developed posterior limb, essentially forming a continuous muscular border, where the His bundle penetrates and crosses the ventricular septum deeply embedded within this muscle. In the majority of anatomic variants, however, the posteroinferior rim of the VSD is wrapped by a rim formed by the confluence

FIGURE 119-1 ■ Graph showing unpublished data on pulmonary valve (PV) anatomy of 101 heart specimens with tetralogy of Fallot (67 belonging to Children’s Hospital in Boston and 34 to the University of Padua). The PV was bicuspid in 65 specimens (65%), tricuspid in 23 (23%), unicuspid in 12 (12%), and quadricuspid in 1 (1%).

FIGURE 119-2 ■ Graph showing unpublished data on pulmonary valve (PV) anatomy of 101 heart specimens with tetralogy of Fallot (67 belonging to Children's Hospital in Boston, and 34 to the University of Padua). The PV cusps were normal in 53 specimens (53% of all cases).

FIGURE 119-3 ■ Anatomic image of a specimen with tetralogy of Fallot showing the inflow and the outflow tracts of the right ventricle, including the infundibular septum (*asterisk*), malalignment ventricular septal defect (VSD), pulmonary valve (PV), and tricuspid valve (TV). (Courtesy Professor Gaetano Thiene.)

of the membranous septum, attachment of the tricuspid valve, and the aortic valve annulus (perimembranous malalignment VSD).^{29,33-35} The posteroinferior limb of the septal band is hypoplastic and therefore does not extend to the posteroinferior border. In this case, the His bundle penetrates and traverses the septum near the fibrous posteroinferior rim of the VSD, being at risk of injury during VSD closure, particularly when the anterior and septal TV leaflets are scarcely developed.

In a small subset of patients, the infundibular septum is extremely hypoplastic or even macroscopically absent. Consequently, the aortic and pulmonary valves are in anatomic fibrous continuity, and the VSD is positioned mostly within the subpulmonary area.

Up to 15% of patients have additional VSDs, which are usually single and muscular, residing mostly within the anterior portion of the ventricular septum.³⁶⁻³⁷ In rare cases, an additional VSD exists in the inlet portion of the septum. Since the His bundle is within the bridge of muscular tissue separating the two VSDs, closure of such defects can be at risk for conduction disturbances.

FIGURE 119-4 ■ Anatomic image of a specimen with tetralogy of Fallot showing in detail the anterior deviation of the infundibular septum (*asterisk*) and the malalignment ventricular septal defect (VSD). (Courtesy Professor Gaetano Thiene.)

Main Pulmonary Artery and Branch Pulmonary Arteries

The main pulmonary artery (MPA) and its right and left branches are smaller caliber than normal; localized stenosis is most often confined to the origin of the left branch, believed to be due to ductal tissue constriction or iatrogenic located at the level of previous systemic/pulmonary arteries shunts anastomosis.^{34,36} In TOF and pulmonary stenosis, the pulmonary trunk and branches are rarely in discontinuity and arborization abnormalities of either left or right pulmonary artery branches are equally rare. It must be emphasized that, in the absence of major aortopulmonary collateral arteries, the pulmonary artery (PA) branches in TOF are almost never prohibitively hypoplastic, even in the presence of severe narrowing of the RVOT, and therefore remain candidates for complete repair.

Coronary Arteries

Coronary arteries anomalies are present in 5% to 12% of patients with TOF.³⁷⁻⁴¹ Most frequently, the left

FIGURE 119-5 ■ The deviated infundibular septum (*asterisk*) and the narrow right ventricular outflow tract (RVOT). AOV, Aortic valve; PV, pulmonary valve; VSD, ventricular septal defect.

FIGURE 119-6 ■ Anatomic image of a specimen with tetralogy of Fallot showing the deviated infundibular septum (*asterisk*) and the narrow right ventricular outflow tract (RVOT). AOV, Aortic valve; PV, pulmonary valve. (Courtesy Professor Gaetano Thiene.)

anterior descending coronary artery (LAD) arises from the right coronary artery (RCA) and traverses the RVOT at various distances from the PV annulus. This anomaly is of great importance for the surgeon to avoid transection or distortion during repair. A transannular incision is at risk under this circumstance. Other coronary artery

anomalies encountered in TOF include: origin of RCA from the left coronary artery; left coronary artery from the MPA; a single coronary artery originating from the left coronary sinus; and an accessory LAD from the RCA.³⁷ Rarely, significant LAD coronary artery branches from the RCA cross the RVOT within the infundibular muscle and are therefore not visible on the epicardial surface, making injury of these arteries possible at the time of repair.

These coronary artery anomalies are more likely to occur in severe forms of TOF, such as coexisting with severe MPA hypoplasia and anterior and lateral rotation of the aorta.⁴¹

Significant coronaries abnormalities can be frequently detected preoperatively with two-dimensional echocardiography, and surgical management can be modified during repair to avoid injuring these vessels.³⁷

PHYSICAL EXAMINATION

When children are admitted electively, during early infancy, they usually exhibit a good clinical state, with no or mild cyanosis (transcutaneous oxygen saturation is often greater than 80%). Cyanosis can be more than mild in the very severe forms or in older children who are presenting late with a progressive myocardial compensatory hypertrophy and significant arterial collateral vessels.

On examination of the heart, the second heart sound is often single and accentuated because of anteriorization of the aortic root. A moderate intensity midsystolic ejection murmur is heard loudest in the second and third intercostal space. Rarely in the less severe forms, TOF can present with signs of increased pulmonary blood flow.

Blood sampling to determine the presence of deletion on the long arm of chromosome 22q11 is part of the routine workup to provide the opportunity for genetic counseling and to identify other organ systems that are frequently involved, as summarized by the acronym CATCH-22 (cardiac disease, abnormal face, thymic hypoplasia, cleft palate, and hypocalcemia).

MEDICAL MANAGEMENT

Since the introduction of early repair of TOF, the preoperative medical management has lost its important role in treating cyanotic children with TOF. Children are usually asymptomatic for the first 2 to 3 months after birth. Cyanosis usually progresses with spells in older children. A cornerstone of the preoperative management is maintaining these infants in well-hydrated state and to avoid contacts to protect them from viral infections. Beta blockers can be used to treat or prevent cyanotic spells. Nevertheless, early repair can avoid most of these complications by restoring a “normal” circulation. Balloon angioplasty and stenting of the RVOT has been recently developed as a palliative procedure for insuring adequate pulmonary blood flow, particularly in those centers where surgical correction in neonates and young infants is postponed (see [Palliations](#)).

DIAGNOSTIC STUDIES

Cardiac catheterization is seldom necessary for assessing the surgical anatomy, except to rule out the presence of major aortopulmonary collateral vessels, often suspected in children who are relatively pink, despite a severe obstruction of the RVOT⁴² or to confirm the echocardiographic diagnosis of coronary artery anomalies (Figs. 119-7 and 119-8).

Two-dimensional echocardiography has become the gold standard to define most details required for surgical correction. A prenatal echo diagnosis is nowadays often

FIGURE 119-7 ■ Preoperative angiographic image showing a large conal coronary artery branch (arrow) originating from the right coronary artery (RCA) and crossing the right ventricular infundibulum. (Courtesy Professor Ornella Milanese.)

FIGURE 119-8 ■ Preoperative angiographic image showing the left coronary artery selective injection. The arrow indicates the anomalous origin of the right coronary artery (RCA) from the left anterior descending coronary artery (LAD) crossing the right ventricular infundibulum.

available and it is usually reconfirmed, soon after birth.⁴³⁻⁵¹ Two-dimensional echocardiography and Doppler in TOF is routinely used for delineating the important features of the malformation and for supplying the surgeons all relevant information essential for achieving a proper repair.

In the long-axis view, the degree of overriding of the aortic valve across the VSD is assessed (Fig. 119-9). The anterior muscular septum is also interrogated to rule out any additional muscular anterior VSDs.

In the parasternal short-axis view, the degree of displacement and length of the infundibular septum is well seen together with all the pertinent anatomy related to the RVOT obstruction, including level of obstruction, type, and severity (Figs. 119-10 and 119-11). In this projection, the PV annulus, MPA, and branches are visualized and measured (see Figs. 119-10 and 119-11). Pulmonary arteries discontinuity or stenosis (particularly at the LPA origin) are usually well identified in this projection. In the absence of localized stenosis, hypoplastic pulmonary arteries very rarely contraindicate total repair (see *Anatomy and Physiology*).

Excellent anatomic images are also obtained from a right or oblique subcostal view. This projection is important for gathering additional information concerning the anatomy and degree and level of RVOT obstruction. Pulmonary valve anatomy, MPA and its branches are also clearly visible and measurable using this projection (Fig. 119-12).

In an apical four-chamber view, the VSD is also well visualized and sized. The muscular septum is screened to rule out any additional VSD. Through a short parasternal axis view, at the base of the heart, both coronary arteries are visualized to exclude any anomaly in origin of the LAD and of major branches of the RCA, including crossing of the RV infundibulum.

FIGURE 119-9 ■ Preoperative two-dimensional echocardiographic image, long-axis view, showing the degree of overriding of the aortic valve across the ventricular septal defect (asterisk). AOV, Aortic valve; LV, left ventricle; RV, right ventricle. (Courtesy Professor Ornella Milanese.)

The presence of abnormal coronary origin or course (see anatomy) is detected with two-dimensional echocardiography and Doppler, particularly for young infants and neonates, when coronary arteries are readily visible.⁵²

SURGICAL TREATMENT

Palliations

A modified Blalock-Taussig (B-T) shunt is still the preferred palliation, in many centers, in the presence of contraindications for primary repair, which are usually dictated by local preferences and experiences. The approach is through a right or left thoracotomy, for

interposing a tubular graft between the right subclavian artery (or innominate artery) or left subclavian artery, and the ipsilateral PA branch. There is a recent trend in approaching these structures through a midline sternotomy, with cardiopulmonary bypass (CPB) on standby (for achieving a total exposure of both PA branches and for better controlling episodes of hemodynamic instability).

Another palliative shunt can also be achieved by interposing a short segment of a tubular graft connecting the ascending aorta and the main pulmonary artery, with the aim of avoiding any distortion to the small and fragile PA branches.

Other palliative alternatives have been introduced by interventional cardiologists, such as stenting of the RVOT.^{53,54} This procedure can be effective for delaying complete repair and for limiting increasing cyanosis and spells. Stenting of the RVOT, however, will inevitably trigger the formation of scar tissue and possibly distortion of PV, rendering the RVOT anatomy more difficult at the time of definite repair.⁵⁵

A patent ductus arteriosus is rarely present in the absence of PV atresia. However its patency can also be maintained with transcatheter stenting when repair is to be delayed.

Repair

The timing of complete repair is still controversial and varies from center to center. Nevertheless the worldwide trend favors early repair, just as for many other complex congenital heart lesions.⁵⁶⁻⁶¹

Complete early repair has been advocated to avoid:

1. Chronic cyanosis and spells
2. Systemic-to-pulmonary artery shunts and their consequences
3. Chronic RV pressure overload and myocardial compensatory hypertrophy (which requires a more extensive resection, at the time of the repair)

4. Hospital costs and offering patients one instead of two operations

Early repair will also establish a permanent physiological circulation, including a normal O₂ saturation, which will avoid the negative effects of cyanosis (and possible cyanotic spells) upon the cerebral nervous system and other developing organs.¹³

Techniques of Complete Repair

Anesthetic Management

Anesthetic management is critical for avoiding cyanotic spells during preparation and induction. A transesophageal or epicardial two- or three-dimensional echocardiogram and Doppler can be used to recall the preoperative images to the surgeon,⁵⁸ and for monitoring the heart performance before and after repair. At the end of CPB, detection of possible residual lesions and then immediate repair are of paramount importance, before transferring patients to the intensive care unit.

Surgical Access

Repair is performed via a median sternotomy. A partial division of the sternum can also be used, particularly in the less severe forms or for bigger children, according to the surgeon's preference. A large segment of anterior pericardium is harvested and treated with the glutaraldehyde used for VSD patch closure, RVOT reconstruction, MPA or branch enlargement, or PV leaflets extension. Total CPB is established by aorta and double caval cannulation. A left ventricular vent is usually placed through the interatrial sulcus, guided into the LV, placed on suction to achieve a bloodless field. Moderate hypothermia is usually induced, according to center or surgeon preference. During the cooling phase, the MPA is dissected from the aorta and its branches are explored. Right pulmonary artery and left pulmonary artery branches are then occluded distally with a Silastic double loop, to avoid blood return from the bronchial arteries which can be disturbing, particularly in very cyanotic children. On a beating heart, the MPA is incised longitudinally. The PA branches are explored and sized. The PV is inspected and sized to assess the effective PV orifice diameter. The heart is then stopped by aorta cross-clamping and by injecting cardioplegia into the aortic root. The right atrium (RA) is incised above the tenia sagittalis, parallel to the atrioventricular groove, and the whole anatomy of the RA cavity is visualized. The fossa ovalis is inspected and the presence of a foramen ovale (or an atrial septal defect) is assessed. The tricuspid valve (TV) is then retracted and the whole RV anatomy is carefully inspected, with particular attention to the size and type of the VSD (malalignment muscular, malalignment perimembranous) and the whole RVOT up to the PV annulus. The subpulmonary fibromuscular obstructions are then resected through the TV. Particular care is taken to remove any subpulmonary muscular obstruction up to the subannular level.

Further resection of the distal part of the RVOT can be achieved through the PV annulus, aiming to enlarge

the whole RV outlet, up to the PV hinges. The VSD is then patch closed with continuous suture or interrupted stitches, according to the surgeon's preference. Particular care must be taken not to damage the aortic valve (the aortic valve can be better visualized through the VSD and protected by delivering short injections of cardioplegia). To facilitate the VSD closure, significant TV chordae crossing the VSD can be detached at their base, and then reattached in the same position, at the end of the VSD patch closure. The TV is then hydrodynamically tested by gentle injection of cold saline solution into the RV cavity. Any possible TV distortion must be repaired, with the aim of preserving long-term TV performance and RV functional integrity.

The foramen ovale, when present, can be left open to reduce the RV preload by allowing right-to-left shunting during the early postoperative period, when the RA pressure is not uncommonly higher than the left atrial (LA) pressure. Before RA closure, cold saline solution is injected through the foramen ovale into the LA and left ventricle (LV), for clearing the LV of air through the cardioplegia needle in the ascending aorta. During the re-warming phase, the PV valve is again inspected. This maneuver can be achieved on a beating heart during re-warming. When a transannular patch is needed, PV competence can be obtained by adding a "new cusp" of biological or prosthetic material. We have used in small children a RVOT patch bearing a valve cusp that is obtained by a divided adult size pulmonary homograft. An LA line is preferably inserted via the previous LA vent purse string. Temporary ventricular and atrial pacing wires are placed on the epicardium, and the patient is weaned from CBPB transesophageal (or epicardial) echocardiography monitoring before decannulation is routinely performed for detecting any possible residual lesions and for assessing the RV and LV performance. Right ventricular pressure can be directly measured by RV puncture, and compared with the LV pressure. Residual dynamic mild obstruction can be predicted to decrease within the 24 to 48 hours following repair.

SPECIAL TOPICS IN SURGICAL MANAGEMENT

Anomalous Coronary Patterns

Conventional repair is complicated by the occurrence of the LAD coronary artery originating totally or in part (dual LAD coronary pattern) from the RCA with the arterial supply from the right coronary artery crossing the RVOT.⁶²⁻⁶⁸ Achieving adequate relief of the RVOT obstruction while maintaining the integrity of the coronary supply requires an understanding of different surgical options and flexibility in their application. Conduit reconstruction of the RVOT with origin from a ventriculotomy placed below the anomalous coronary has given reliable results but ultimately necessitates reoperation for conduit replacement. Translocation of the pulmonary artery to a distal ventriculotomy and use of the native pulmonary artery as a composite conduit to create a double outflow from the right ventricle have also been

used successfully.⁶⁴⁻⁶⁷ The transatrial transpulmonary approach has been especially successful in dealing with this difficult anatomy.^{65,66} Brizard and coworkers⁶⁵ reported on Duncan's approach in 36 patients, which allowed a conduit to be avoided in all but two cases. Twenty-five patients required a limited transannular patch that was slightly deviated, when necessary, to avoid injuring the anomalous coronary artery. There were no perioperative or long-term deaths, and postoperative right ventricular pressures were low and equivalent to those obtained in contemporaneous patients undergoing TOF repair without coronary anomalies. There was also no difference in reoperation rates for patients with or without anomalous coronaries.⁶⁵ A more recent report provided evidence that adequate relief of RVOT obstruction can usually be performed with a relatively straightforward approach to patch reconstruction without the need for conduits or translocation of the coronary artery.⁶⁸

Use of a Monocusp Valve in Reconstruction of the Right Ventricular Outflow Tract

Monocusp reconstruction of the RVOT (Fig. 119-13) can be achieved by sawing a triangular shape of tissue from the distal part of the ventriculotomy, up to the margin of the natural PV leaflets, using either autologous pericardium or heterologous tissue or prosthetic material (polytetrafluoroethylene [PTFE]). Reports vary regarding the usefulness of monocusp valve reconstruction for the RVOT.⁶⁹⁻⁷⁴ Augmentation plasty of the PV leaflets, by adding an additional cusp can avoid PV regurgitation, early postoperatively, improving the short-term clinical

outcome. Nonetheless, when a cusp needs to be added, leaflet function often deteriorates over time, resulting in a progressive PV regurgitation. When pericardium or PTFE are used to create a monocusp, the valve function is probably limited to the first weeks to months after repair, but the mode of valve failure (adherence of the monocusp to the RVOT patch) is never obstructive.^{69,71} Our unpublished experience with adding a prosthetic cusp material shows that a better short and mid-term performance is achieved with a "built-in" cusp obtained from an adult size pulmonary homograft when compared with other biological added material.

Preservation of the Pulmonary Valve

The use of a transannular patch, necessary in some cases, often results in pulmonary insufficiency with chronic RV volume overload, leading inevitably to progressive RV dilation and dysfunction which is associated with impaired functional capacity. The interest in preserving PV function has stimulated surgeons to devise valve-sparing techniques for TOF repair. During the last few years, some centers have combined the routine correction of TOF with intraoperative balloon dilation of the hypoplastic pulmonary annulus⁷⁵⁻⁷⁹ in selected cases. At the time of repair, the PV is usually inspected and sized to assess the effective PV orifice diameter. In the presence of a stenotic PV, a valvar commissurotomy is performed at each commissure, down to the sinotubular junction. After this maneuver, the valve is again sized to measure the true annular diameter.

Particular care is taken to remove any possible RVOT obstruction up to the subannular level by combining transatrial, transtricuspid muscle band resection and a further transpulmonary residual muscle band excision through the PV annulus, before and after balloon dilation.

Only after a satisfactory muscle bundle resection is achieved, a high pressure, appropriate size, valvuloplasty balloon catheter is introduced through the TV across the PV orifice and inflated under direct vision,^{77,78} while securing its tip, until the inner pressure reaches 10 atm (Fig. 119-14). We use short (2 cm), high-pressure (>10 atm), noncompliant balloons sized according to the calculated size of the PV orifice relative to the body surface area of the patient. When the PV effective orifice is particularly narrow (z-score < -3), we use an "in-series

FIGURE 119-13 ■ **A**, The native hypoplastic pulmonary valve in a patient with tetralogy of Fallot. **B**, The native pulmonary valve after transannular incision. **C**, The monocusp-patch augmentation (asterisk) of the right ventricular outflow tract.

FIGURE 119-14 ■ **A** and **B**, Cartoon showing the intraoperative balloon dilation of the pulmonary valve. It is notable that, because of the transatrial approach, the balloon catheter is inserted through the right atrium (RA) and tricuspid valve (TV) into the pulmonary valve annulus. **C**, Intraoperative details of the balloon catheter through the pulmonary valve.

balloon dilation strategy” by using increasing diameters of balloons for allowing a progressive stretching and dilation of the PV annulus up to the ideal size according to body surface area. While dealing with a highly hypoplastic PV annulus (z-score range, -3 to -4), the PV leaflets, which are often separated by the balloon dilation at the commissure level, are then reconstructed by carefully delaminating them with a fine scalpel at the PV hinge point and down to the RV epicardium, thus extending the leaflets coaptation area (Figs. 119-15 through 119-17). Subsequently, the extended leaflets are “re-suspended” either directly or after further augmentation with small prosthetic (biologic) patch material. An appropriate Hegar dilator for PV size (PV z-score = 0) is passed through the new PV annulus. The MPA is eventually patch enlarged, when needed, with an autologous pericardial patch that is anchored proximally below the PV annulus, onto the RVOT epicardium, with the aim of avoiding any potential early or late constriction over the reconstructed PV apparatus (Fig. 119-18). In case the PV anatomic integrity cannot be preserved, a transannular incision is performed into the distal part of the RVOT.

CONTROVERSIES IN SURGICAL MANAGEMENT

Ventriculotomy versus Transatrial-Transpulmonary Approach

Excellent exposure of the VSD and obstructive muscle bundles in the RVOT can be achieved through either a right ventriculotomy or through an incision in the right atrium.^{11,13} An approach through a right ventriculotomy (Fig. 119-19) is still preferred, in many centers.⁸⁰⁻⁸⁶ Access to the VSD, and to obstructing muscle bundles of the RVOT is more easily achieved by incising longitudinally the RV infundibulum. After muscle bundle resection, the VSD is patch closed either with interrupted stitches or continuous suture. In light of the long-term results that reveal a chronic RV dysfunction after “pioneeristic” TOF repair, which was routinely achieved by means of a “generous” ventriculotomy, there is now a common trend in limiting the right ventriculotomy for, as much as possible, limiting in this way the RV geometry distortion. In addition, some groups have reported a lower incidence of recurrent RVOT obstruction in lesions corrected through the RV ventriculotomy.⁸⁷⁻⁸⁹

Approach through a RA incision (Fig. 119-20) and, when necessary, a combined incision in the pulmonary artery avoids a ventriculotomy and may help to avoid RV dysfunction after repair, especially in the immediate post-operative period and in the very young heart.⁹⁰⁻¹⁰⁰ Miura and coauthors⁹² demonstrated better preservation of right ventricular function at baseline and in response to catecholamine infusion in patients who had undergone a transatrial transpulmonary approach than in those with a right ventriculotomy. In 1995 Stellin and colleagues⁵⁸ demonstrated a trend toward a reduced RV volume and a better ejection fraction in the long term after transatrial repair, when compared with a classic transventricular repair. If a transannular patch is required, a limited right ventriculotomy extending only a few millimeters below the pulmonary annulus is possible.^{58,101} Minimizing or eliminating a right ventriculotomy altogether by using a transatrial or combined transatrial transpulmonary approach may also reduce the substrate for ventricular arrhythmias arising from incisions in the right ventricle.

Timing of Operation

The predominant trend in the timing of surgical intervention has been toward earlier intervention with elective repair in the first 4 to 6 months of life.^{56-60,102-115} There is less consensus regarding the best treatment for patients who become symptomatic early in infancy or in the neonatal age. Some advocate primary repair in symptomatic infants regardless of age.^{114,115} Whereas some centers have adopted a policy of elective repair for all infants at the time of presentation, even for neonates.^{96,104,107,116,117} Advocates of early primary repair note that this approach limits the duration of exposure of these children to cyanosis and its attendant cumulative complications. In addition, initial complete repair avoids the attrition that can

FIGURE 119-19 ■ The intraoperative phases of the transventricular tetralogy of Fallot repair. **A** and **B**, The ventricular septal defect (VSD) is visualized and closed through the right ventriculotomy. **C**, The right ventricular outflow tract and the main pulmonary artery are eventually patch augmented.

FIGURE 119-20 ■ The intraoperative phases of the transatrial tetralogy of Fallot repair. **A–C**, The ventricular septal defect (VSD) is visualized and closed through the right atrium after **(B)** a combined transatrial/transpulmonary myotomy and myectomy of the right ventricular (RV) outflow tract.

occur during the time between initial placement of a systemic-to-pulmonary arterial shunt and full repair in patients who undergo a staged approach. Furthermore, it has been postulated that ongoing pressure loading of the RV, in combination with chronic hypoxia, creates a substrate in the RV myocardium that predisposes to arrhythmia and diastolic dysfunction in patients who undergo later complete repair.¹⁰⁸ Some authors have reported primary repair of TOF in early infancy with mortality rates as low as 3%.⁸⁰ Nevertheless, primary repair in early infancy has been shown to require transannular patch placement as part of the repair in a higher percentage of

patients and to require longer stays in the intensive care unit.^{113–115} Excellent results have also been achieved with approaches that selectively use systemic-to-pulmonary arterial shunting as initial palliation for symptomatic neonates and young infants.^{1,90,94} Proponents of this approach cite that mortality and morbidity are higher in the youngest infants in many series that report success with early primary repair. The neonatal myocardium may be less capable of handling the RV volume overload that follows VSD closure in a cyanotic patient, and this can be exacerbated by the additional RV volume loading from pulmonary incompetence and possible tricuspid valve

(TV) incompetence in a heart that has undergone the ischemic period required for surgical repair. Well-executed shunting in early infancy for TOF carries a very low risk of pulmonary artery distortion or early or interval mortality.^{94,96,118} Fraser and colleagues⁹⁶ reported on selective application of primary repair for patients larger than 4 kg, with initial shunting of smaller patients who required earlier attention because of symptoms or anatomy. Although the majority of patients had TOF with pulmonic stenosis, this series also included patients with TOF and pulmonary atresia and patients with TOF and an AV septal defect. A single-shunted patient with TOF and a complete AV septal defect died in the interval before primary repair, but there were no perioperative deaths at the time of complete repair. Patch reconstruction of the RVOT either with a fenestrated VSD patch or without any attempt to close the VSD can be performed as an alternative to systemic-to-pulmonary arterial shunting in symptomatic patients with TOF and diminutive pulmonary arteries.^{119,120}

POSTOPERATIVE MANAGEMENT

The majority of patients have a relatively uncomplicated postoperative course. Inotropic support is usually provided with low doses of dopamine, and extubation is generally possible during the first 12 to 48 hours after surgery. Right ventricular dysfunction as a cause of low cardiac output in the immediate postoperative period is rarely seen, especially when the PV integrity is preserved.¹²¹ Significant diastolic dysfunction of the RV after TOF repair can produce a “restrictive physiology” in which the stiff RV demonstrates inadequate filling and can behave almost like a passive conduit for pulmonary blood flow.^{108,122,123} The causes of RV dysfunction include PV, the presence of a right ventriculotomy, and residual lesions such as a hemodynamically significant VSD or RVOT obstruction. Right ventricular dysfunction is apparent by elevation in the RA pressure along with the accompanying clinical manifestations of liver enlargement, edema, and effusions in a patient with evidence of low cardiac output (decreased cutaneous temperature, elevated lactate levels, decreased urine output). Right ventricular dysfunction after TOF repair is usually transient and responds to increased inotropic support and diuretics. A patent foramen ovale (or a calibrated atrial septal defect) allows right-to-left shunting at the atrial level with decompression of the right heart chambers at the expense of a slight arterial oxygen desaturation. A progressive increase in the oxygen arterial saturation can be interpreted as an improvement in the RV performance in the early postoperative period. Junctional ectopic tachycardia (JET) can occur after TOF repair, especially in the first few hours after surgery.^{58,78,86} When it does occur, postoperative JET is characterized by atrioventricular dissociation with rapid junctional rates of up to 230 beats per minute. In a recent report, JET occurred in 22% of patients who had undergone TOF repair,^{124,125} with resection rather than simple transection of muscle bundles within the RVOT, a higher bypass temperature, and a transatrial approach to VSD closure were all

associated with a higher incidence of postoperative JET. The authors concluded that avoidance of excessive muscle resection in the RVOT and traction during VSD exposure should reduce the incidence of postoperative JET. Treatment of JET includes core cooling (34–35° C), reduction in inotrope dosages, atrial pacing above the junctional rate, and the administration of antiarrhythmic agents.^{126,128} Also loading with amiodarone over 2 to 4 hours, followed by continuous infusion, is a useful pharmacologic approach to JET after TOF repair.^{126,128} We have found that an induced surface hypothermia (rectal temperature of 34–35° C) is a useful tool for treating a low output syndrome, particularly when in combination with arrhythmias.

Residual lesions after TOF repair include residual VSDs and significant RVOT obstruction. Even small residual VSDs (3–4 mm) that would be well tolerated in patients with repaired large left-to-right shunts (VSD, truncus arteriosus) may be poorly tolerated after TOF repair. Poor tolerance of residual left-to-right shunts after TOF repair can result from a combination of factors including coexisting pulmonic regurgitation, noncompliant ventricles, and sudden volume loading of the left ventricle, particularly in neonates and young infants.^{121–123,129} The presence of a residual VSD should be ruled out using intraoperative transesophageal or epicardial echocardiography. Patients with significant VSDs will demonstrate a higher than expected LA pressure. If a pulmonary artery catheter is in place, an oxygen saturation of greater than 80% in pulmonary arterial blood is predictive of a hemodynamically significant residual VSD.^{121,129} Significant residual RVOT obstruction is usually tolerated in the immediate postoperative period, but late problems including ventricular tachyarrhythmias and the need for late reoperation occur more commonly.¹³⁰ Hemodynamic instability arising from residual VSDs or RVOT obstruction may also be attributed to postoperative RV dysfunction alone, therefore residual lesions should be aggressively ruled out in patients with poor postoperative hemodynamics. An accurate intraoperative echocardiographic assessment is essential for ruling out any important residual lesion, before transferring the patient to the intensive care unit.

LONG-TERM FOLLOW-UP

Currently, surgery for TOF repair has reached excellent early and late outcomes in either neonates or children.¹³⁰ Decisions made at the time of surgery have a definite effect on the performance of TOF repair in the long-term follow-up. Despite institutional differences in surgical approach, timing of surgery, and many other aspects of management, long-term outcomes in survivors of TOF repair are uniformly favorable. Alexiou and colleagues¹⁰³ reported a 20-year survival of 98% after TOF repair, with 99% of survivors in New York Heart Association (NYHA) functional class I. Knott-Craig and coworkers¹³¹ reported a 20-year survival of 98% with 86% freedom from reintervention on the RVOT after 20 years of follow-up. Katz and coauthors¹³² demonstrated an 8-year actuarial survival of 96% after TOF repair, with

98% freedom from reoperation. In this study, older age at surgery, an increased ratio of RV to LV pressure, and the use of a preceding Potts shunt were all risk factors for late events. The use of a transannular patch during repair or a Blalock-Taussig shunt before repair were not associated with adverse late events. Murphy and associates¹³³ found a 32-year actuarial survival of 86%, which was less than the expected rate of 96% in age-matched controls. In this report, the authors also found that age at operation beyond 12 years and an elevated ratio of RV/LV pressure is associated with late mortality, whereas the presence of a transannular patch or a Blalock-Taussig shunt was not a significant risk factor for late mortality. Mimic and associates¹³⁴ from Great Ormond Street, have recently reported their experience with TOF repair, confirming that age at repair was not linked to early clinical outcome or reoperation/reintervention rate, and that palliative procedures postponed the timing of complete repair, but did not increase the reintervention rate. Kobayashi and coworkers¹³⁵ reported that 85% of patients had no more than mild TV regurgitation during a mean follow-up of 7 years after repair and that the development of moderate to severe TV regurgitation was independent of the operative approach used (transatrial versus transventricular) but was associated with significant pulmonary regurgitation and elevated right ventricular pressure. As a result of these improved results, currently there are an increasing number of patients with repaired TOF who reach adult age.^{133,136} Thus, new problems have recently arisen other than survival to surgery: RV dysfunction and exercise intolerance, arrhythmias and sudden death, and importantly, pulmonary valve regurgitation requiring replacement.

Right Ventricular Performance and Functional Status

Right ventricular dysfunction can occur in the long term as a result of pulmonary regurgitation, a large right ventriculotomy, and eventual residual lesions.¹³⁷ In the hope of decreasing long-term complications of conventional transventricular repair, a transatrial/transpulmonary approach with limited (<1 cm) transannular right ventriculotomy has been adopted by many centers.^{58,60,138} Nevertheless, benefits of this technique on RV performance in the long term are still not clearly demonstrated. Van den Berg and colleagues⁹⁸ have studied using magnetic resonance imaging (MRI), electrocardiography, and stress test in a cohort of 59 patients treated for TOF with a transatrial transpulmonary approach. At a mean follow-up time of 14 years, when compared with current data on healthy controls, TOF patients had significantly larger RV end-diastolic and end-systolic volumes and smaller RV and LV ejection fraction. In addition, maximum oxygen consumption was $97\% \pm 17\%$ and maximum workload $89\% \pm 13\%$ of predicted. Despite well-preserved clinical conditions, these patients exhibited RV dilation and dysfunction associated with impaired functional capacity. Sfyrdis and colleagues¹³⁸ analyzed early and late results of transatrial/transpulmonary TOF repair over almost 14 years, with the aim of assessing the long-term RV function. Among 245 consecutive patients

FIGURE 119-21 ■ Magnetic resonance imaging at follow-up. Three-dimensional reconstruction shows the dilated right ventricle (RV) and main pulmonary artery (MPA). with repaired TOF (median age, 1.6 years), at a median follow-up of 8.5 years, there were no operative deaths, and only three early reoperations. Actuarial survival at 14 years was 98.8%, but 25 patients required late reoperation (mostly for pulmonary valve implantation). All survivors were asymptomatic at follow-up, and right ventricular function was reported within normal limits in most patients. Cheul and associates¹³⁹ have recently reported results from MRI (Fig. 119-21) comparing patients after a transatrial versus a transventricular TOF repair, with the aim of demonstrating whether a transatrial approach would result in less RV dilation and dysfunction, in the long term. Although the two groups differed significantly in follow-up time (12.7 ± 3.8 years vs. 17.2 ± 4.7 years; $P < 0.001$), pulmonary regurgitation fraction, indexed RV volumes and RV ejection fraction were not significantly different.

The importance of preserving the pulmonary valve function to permit a better RV late outcome has been investigated by different authors.^{75-78,140,141} Recently, our institution has reported⁷⁷⁻⁷⁸ the midterm results of 39 patients after early transatrial repair and an attempt of pulmonary valve preservation by intra-operative balloon dilation of the pulmonary valve annulus. Of these, 34 underwent a successful preservation of the pulmonary valve, at a median age of 3.8 months. Pulmonary regurgitation was absent or mild in 88% at discharge. At a median follow-up time of 1.2 years (range, 0.5-5.3 years) the integrity of the PV seemed to achieve improved RV function in comparison to patients who underwent a classical transannular patch.⁷⁸

The performance of TOF repaired patients during exercise testing is also well maintained as reported by several authors.¹⁴¹ Mahle and colleagues¹⁴² reported that

the mean maximal VO_2 of patients after conventional TOF repair was 95% of the predicted mean value for a control population, and the mean maximal work rate was 98% of predicted. In this study, the age of repair (<1 year of age versus >1 year of age) showed no effect on exercise performance, which is an important finding for decisions regarding timing of repair. Kondo and colleagues¹⁴³ found that cardiac output was normal at rest and during exercise in patients after repair, but that the incremental increase in left ventricular ejection fraction during exercise was reduced. The authors hypothesized that RV enlargement with pathologic changes in the septum (e.g., fibrosis) causes latent left ventricular dysfunction during exercise in these patients. Mueller and associates¹⁴⁴ investigated health-related quality of life (QOL) in children after TOF repair, and they compared the self-reported physical ability with objective exercise performance. This study included 168 patients, aged 8 to 16 years. Health-related QOL and cardiopulmonary exercise capacity were compared with those of an age-matched standard population, and correlations of health-related QOL with self-estimated physical rating and cardiopulmonary exercise capacity were analyzed. Despite health-related QOL in children and adolescents after TOF repair, results indicated no limitations; objective exercise capacity was actually impaired when compared with the standard population. Thus, the self-estimated physical functioning result was significantly overestimated compared with actual exercise capacity.

Arrhythmias and Sudden Death

Supraventricular and ventricular arrhythmias are not uncommon late after TOF repair; however, they can occur with increasing frequency as the duration of follow-up increases.¹⁴⁵⁻¹⁵⁵ Various studies have reported that in patients followed for more than 20 years after TOF repair incidence of arrhythmias requiring treatment was 2% to 4% for atrial fibrillation or flutter, 3% to 4% for sustained ventricular tachycardia, and 2% to 4% for sudden cardiac death.^{148,152,153,155} Holter monitoring detected a higher percentage of arrhythmias, with one report demonstrating that 19% of patients had sustained ventricular tachycardia and 23% of patients had atrial fibrillation or flutter on 24-hour Holter monitoring.¹⁴⁹ After TOF repair, the occurrence of arrhythmias is associated with elevated RV volumes and pressure, decreased right and left ventricular ejection fractions, pulmonic regurgitation, and other pathology of the RVOT such as aneurysm or significant stenosis.^{127,150-154,156} Gatzoulis and associates found that PV regurgitation was associated with ventricular tachycardia and sudden death, whereas TV regurgitation was associated with atrial fibrillation or flutter.¹⁴⁸ In addition, they demonstrated that a substantially widened QRS complex on ECG is a prognostic marker of ventricular tachycardia and sudden cardiac death, with a QRS duration greater than 180 msec sensitively predicting the occurrence of life-threatening ventricular ectopy.^{148,155} Dietl and coauthors¹²⁷ found that the type of operative approach for TOF repair was associated with significant ventricular ectopy after surgery. In fact, they reported that 39% of

patients had significant ventricular ectopy after a ventricular approach to TOF repair, whereas only 2.8% had significant ventricular ectopy after a transatrial approach. In this report, the incidence of moderate to severe pulmonary regurgitation was nearly twice as high in the ventricular repair group (25.9%) as in the transatrial repair group (12.5%). Therrien and colleagues¹⁵³ found that PV replacement, when performed in the presence of important regurgitation and RV enlargement, was associated with a substantial decrease in arrhythmias and stabilization of the QRS duration. These authors used intraoperative electrophysiologic mapping and cryoablation in addition to pulmonary valve replacement in selected cases. In this series, atrial arrhythmias decreased from 17% to 12% postoperatively, and ventricular tachyarrhythmias decreased from 22% to 9%. In the 15 patients who underwent intraoperative cryoablation, there were no postoperative recurrences of significant arrhythmia.

All these studies emphasize that residual hemodynamic abnormalities drive postoperative arrhythmias after TOF repair and that all efforts should be made at the time of repair to provide the anatomic substrate to minimize long-term hemodynamic problems.

In a recent report,¹⁵⁶ atrial reentrant tachycardia is reported to be expected in more than 30% of patients, and high-grade ventricular arrhythmias in about 10%. The overall incidence of sudden cardiac death is estimated at 0.2% per year. Placement of an implantable cardioverter-defibrillator, despite high complications and inappropriate discharges, is often recommended for patients at higher risk. The Mayo clinic group reports that patients with TOF represent up to 40% of candidates for implantable cardioverter-defibrillator therapy.¹⁵⁷ Ongoing surveillance of RV function is a critical component of clinical assessment. Once RV dysfunction occurs, there are no medical therapies that have been shown to be effective, except for resynchronization with biventricular pacing in selected cases.

Late Pulmonary Valve Implantation

Currently, PV implantation is a common procedure during follow-up of patients after TOF repair, that can be done either surgically or percutaneously.¹⁵⁸⁻¹⁶⁰ Timing and indicators for late PV implantation for PV regurgitation after TOF repair are not yet clearly defined and universally accepted.^{36,161-164} MRI has been used increasingly to evaluate RV volumes and function. In most cases, PV implantation can be expected to reduce RV volumes; however, there is a point of RV enlargement beyond which normalization of RV size is unlikely to occur. Several reports support this concept of RV size reduction without normalization when pulmonary valve implantation is performed when RV end-diastolic volume is above 160 to 170 mL/m²¹⁶³⁻¹⁶⁴ or even less.¹⁶⁵ Beyond its impact on RV dimensions, PV implantation reduces tricuspid regurgitation and clinical symptoms, and it often results in improved RV function.^{145,166} The effects of pulmonary valve implantation on QRS duration and the incidence of RV arrhythmia are less well established.^{146,166,167} Based on existing literature, an argument can be made to consider

PV implantation when there is documentation of progressive RV enlargement ($>150 \text{ mL/m}^2$) and RV dysfunction, particularly in the presence of progressive TV regurgitation or decreased exercise tolerance.^{168,169} A number of reports have detailed various clinical aspects of PV implantation in patients after TOF repair.^{145,146,161-164,166-179}

In addition to the standard surgical approach, percutaneous valve implantation has been used increasingly.¹⁵⁸⁻¹⁶⁰ Discigil and coauthors¹⁷² reported on 42 patients who underwent surgical pulmonary valve implantation approximately 11 years after TOF repair. Decreased exercise tolerance (58%), right heart failure (21%), arrhythmias (14%), syncope (10%), and RV dilation (7%) were the main indications for PV implantation. Ninety-eight percent of patients were hospital survivors with 5- and 10-year survival rates of 95% and 76%, respectively. Before surgery, 27% of patients were in NYHA class I or II, and after PV implantation, 97% were in NYHA class I or II. Significant atrial arrhythmias were present in 14% preoperatively and 2% postoperatively. Freedom from repeat PV implantation was 93% at 5 years and 70% at 10 years. Vliegen and coworkers¹⁷⁶ used MRI to evaluate patients before and after PV implantation and found that RV end-diastolic volume and RV end-systolic volume decreased, and RV ejection fraction increased, after PV implantation. As a functional correlate, NYHA class was also found to improve substantially after PV implantation. Despite improvement in RV volumes and functional status after PV implantation, a number of studies demonstrated improvement only if valve implantation was performed appropriately early.^{173,174,177} De Ruijter reported an incidence of severe PV regurgitation of 31% at an average of nearly 10 years after TOF repair, with significant RV dilation in 38%.¹⁷⁴ For patients treated with pulmonary valve implantation, only 44% had normalization of RV size and symptomatic relief. Therrien and coworkers¹⁷³ reported no improvement in RV volumes after PV implantation. In addition, RV ejection fraction remained depressed (<0.4) in 87% of patients in whom preimplantation RV ejection was less than 0.4, whereas 50% of patients with preimplantation RV ejection fraction greater than 0.4 maintained postimplantation RV ejection fractions greater than 0.4. In light of these results, they concluded that late PV implantation failed to normalize RV volumes, and that the best chance of restoring a normal RV function was to perform PV implantation before significant RV dysfunction had occurred. Controversial results were reported by Quail and associates,¹⁴ who studied TOF repaired patients with PV regurgitation. They compared the group of patients treated with PV implantation with matched untreated patients who were eligible for PV implantation based on hemodynamic status. Among 87 patients recruited, 51 underwent surgery while 36 were managed conservatively. Comparing 25 patients from each group using propensity score matching, they found that at 1.8 years of follow-up in patients with intermediate RV dilation, there was a very low risk of significant deterioration in RV or LV volumes and function. They concluded that slow deterioration can guide the interval for repeat imaging studies and determine the appropriate timing for PV implantation. Finally, a recent meta-analysis¹⁸⁰ has

concluded that after PV implantation, there is an improvement of RV volumes and function and of LV function, a reduction of QRS duration, and improvement of symptoms. However, the preoperative RV geometry was capable of modulating the effect of PV implantation. In conclusion, despite important heterogeneity of the effects among the different studies, PV implantation is currently recommended as a reasonable approach to the problem even if surgical timing remains to be further defined and controversies still remain.

Finally, homografts or bioprosthetic valves are usually preferred in the PV position in patients with congenital heart disease.¹⁶¹⁻¹⁶⁵ However, unsatisfactory long-term results have reawakened interest in the use of mechanical valves in the pulmonary position. Waterbolk and associates¹⁸¹ report excellent early and late outcomes of mechanical valve implantation in the pulmonary position in 27 of 79 patients indicated for PV replacement. Tetralogy of Fallot was the most common basic lesion. Thirty-day hospital mortality was 1 of 28 (3.6%), because of a cerebrovascular accident. One patient died late (2.8 years postoperatively). Median age was 33 years, and the median interval between primary repair and insertion of the prosthesis was 26 years. Freedom from reoperation at 1 year was 100%. No thromboembolic events were observed. Recently, Shin and colleagues¹⁸² have investigated the long-term outcomes of mechanical valves implanted in the pulmonic position in 37 patients (median age, 13.5 years; range, 7 months to 23 years) who had undergone 38 mechanical pulmonary valve implantations. Most patients ($n = 23$) had TOF, and the median valve size was 23 mm (range, 17–27 mm). At a median follow-up of 24.6 months (range, 1.3 months to 22.5 years), survival rates were 97%, 97%, and 97%, at 1, 5, and 10 years, respectively. Freedom from thromboembolism or bleeding events was 92%, 92%, and 78.8%, at 1, 5 and 10 years, respectively. Freedom from reoperation was 100%, 100%, and 85.7%, at 1, 5, and 10 years, respectively. Thus they conclude that in growing patients who have undergone prior sternotomies requiring a pulmonary valve replacement, a mechanical valve could be an attractive option. Although life-long anticoagulation therapy is indicated for mechanical prostheses, the chance of subsequent reoperations can be expected to be low.

Further study is necessary for developing an ideal long-standing biological valve in the pulmonary position. Preliminary studies with decellularized pulmonary homograft are promising.¹⁸³⁻¹⁸⁴ A European multicenter ongoing trial will soon report on the use of such a prosthesis, on a larger scale.

Such a new type of tissue engineered valve will certainly show, in the near future, the advantage of treating chronic PV regurgitation in an increasing population after TOF repair in comparison to conventional valve substitutes that are implanted surgically or transcatheterally.

ATRIOVENTRICULAR CANAL AND TETRALOGY OF FALLOT

A common AV valve, an ostium primum atrial septal defect, and a nonrestrictive inlet ventricular septal defect

occur in combination with an anterior malalignment VSD and RVOT obstruction typical of TOF in approximately 2% of all cases of TOF.^{36,185} Repair can be accomplished with a single- or double-patch technique, depending on institutional habits. In addition, transventricular or transatrial transpulmonary approaches can be used successfully.¹⁸⁵⁻¹⁹³ Usually, most or all VSDs can be closed through the right atrium, as is standard for repair of an AV septal defect, but the VSD patch must be shaped appropriately for the peculiarity of this defect; in fact, it has to be elongated and wide enough anteriorly so as to close the anterior extension of the VSD without causing subaortic obstruction. Closure of the cleft in the left-sided AV valve and closure of the ostium primum ASD is performed in a standard fashion, and relief of the RV outflow tract obstruction is performed as would normally be done for TOF. In a recent retrospective analysis from Kotani and colleagues from Sick Children's Hospital in Toronto,¹⁹⁴ of 41 patients who underwent repair for TOF with AV septal defect, only 3 died early. The RV outflow tract was reconstructed, with pulmonary valve sparing in 56%. There was no late death, and survival was 92.1% at 15 years. During a median follow-up period of 5.9 years, freedom from all reinterventions at 15 years was 52.8%; approximately half of those procedures were related to the RV outflow tract revision, whereas only a minority had AV valve dysfunction. Freedom from RV outflow tract-related reintervention and atrioventricular valve/LV outflow tract-related reintervention were comparable between the TOF with atrioventricular septal defect and matched control groups (TOF with atrioventricular septal defect, 95.2% and 88.6% versus atrioventricular septal defect alone, 86.0% and 83.9% at 5 years, respectively; *P* value not significant). Thus, in the current era, the surgically modified history of TOF with atrioventricular septal defect is not significantly different from that of isolated TOF.^{185,187-189,191}

TETRALOGY OF FALLOT WITH ABSENT PULMONARY VALVE

The anatomic features of TOF with absent pulmonary valve include massively enlarged pulmonary arteries, anterior malalignment VSD, absent (aplasia) or rudimentary development of the PV, a relatively small PV annulus, and usually absence of the ductus arteriosus. The etiology of the aneurysmal enlargement of the pulmonary arteries may be related to the effects of regurgitation throughout fetal development, or to abnormalities in the vessel wall. Massive enlargement of the pulmonary arteries frequently causes obstruction of the central bronchi and also alveoli. The degree of airway obstruction dictates the clinical course observed in affected patients. Presentation varies from no clinically significant airway obstruction in asymptomatic patients, to severe bronchioalveolar obstruction requiring mechanical ventilation and surgical repair in the newborn period. Operative repair requires intracardiac correction typical of simple TOF on cardiopulmonary bypass, with surgical reduction in the size of the dilated main and branch pulmonary arteries, that can be

performed by different techniques.¹⁹⁵⁻²¹⁰ In most cases, both the MPA and branches are massively enlarged and must be reduced surgically. Stellin and colleagues²⁰³ advocated surgical intervention to relieve the bronchial obstruction by plicating the pulmonary artery and its branches under deep hypothermia and circulatory arrest. Alternatively, it can be transected with a portion excised posteriorly, which effectively pulls the pulmonary arteries anteriorly away from the tracheobronchial tree. The branch pulmonary arteries are reduced in diameter by resecting portions of the anterior wall, often with plication of the posterior wall.^{197,198,201,202} In most cases, a transannular incision is necessary; reconstruction of the RV outflow tract can then be performed with a homograft valve insertion.^{201,204,206,209} However, RV outflow tract reconstruction can also be performed with a monocusp or, often, without any valve implantation.^{197,198,202,208} McDonnell and coworkers reported an experience with surgical management for 28 patients with TOF and absent pulmonary valve,¹⁹⁷ in which 13 patients (46%) required preoperative intubation and mechanical ventilation. There was a 21% in-hospital mortality, and rates of freedom from death or reintervention at 1 and 10 years were 68% and 52%, respectively. The requirement for preoperative mechanical ventilation was the only risk factor for mortality in this series. Hraska and associates^{196,210} have reported a novel approach to this problem that includes transection and removal of a wedge-shaped portion of the ascending aorta so as to bring the aorta caudally and to the left. A LeCompte maneuver bringing the pulmonary arteries anterior to the aorta is then performed with or without concomitant plication of the branch pulmonary arteries. This approach pulls the pulmonary arteries off the tracheobronchial tree without requiring extensive suture lines, and the method of resection of the aorta creates a space for the new location of the pulmonary arteries while minimizing the risk of compression of the RCA. In a retrospective review of 62 consecutive patients following repair of TOF and absent pulmonary valve, Alsoufi and coworkers²⁰⁶ reported three perioperative deaths in neonates and five late deaths. Five- and ten-year survival was 93% $\pm$ 4% and 87% $\pm$ 5%. On multivariable analysis, significant factors associated with prolonged ventilation were neonatal age (*P* < 0.0001) and preoperative mechanical ventilation (*P* = 0.088). Eight airway reinterventions were needed in seven infants with persistent postoperative airway compromise, pulmonary artery suspension (*n* = 4), innominate artery suspension (*n* = 2), and lobectomy (*n* = 2). Freedom from RV outflow tract reoperation was 89% $\pm$ 5% and 59% $\pm$ 9% at 5 and 10 years, respectively. In conclusion, TOF with absent pulmonary valve remains a complex congenital heart defect, with a perioperative mortality mainly related to a preoperatively compromised bronchial tree, and a higher rate of reintervention in follow-up when compared with classic TOF.

PULMONARY ATRESIA WITH VENTRICULAR SEPTAL DEFECT

Pulmonary atresia with ventricular septal defect (PA/VSD) is a congenital cardiac malformation characterized by discontinuity of blood flow from the right ventricle to the pulmonary arteries, a ventricular septal defect (VSD) resulting from anterior deviation of the infundibular (conal) septum, and an overriding aorta. Because it shares many attributes of tetralogy of Fallot, it is also referred

to as tetralogy of Fallot with pulmonary atresia. Incidence of PA/VSD is estimated to be 1 in 10,000 live births.¹ A right aortic arch may be seen in up to 45% of patients.² PA/VSD is also associated with major aortopulmonary collateral arteries (MAPCAs) that, in some cases, are the sole supply of pulmonary blood flow. The morphology of the pulmonary circulation, which varies significantly among patients, determines the management and prognosis of this malformation. PA/VSD may also be associated with other intracardiac defects, such as tricuspid atresia or stenosis, complete atrioventricular canal,

FIGURE 120-1 ■ Anatomic specimen and schematic demonstrating the features of pulmonary atresia with ventricular septal defect. (Courtesy Children's Hospital Boston.)

complete or corrected transposition of the great arteries, left superior vena cava, anomalies of the coronary sinus, dextrocardia, and asplenia or polysplenia syndrome. These more complex forms of PA/VSD are not discussed in this chapter. The most common associated genetic defect is 22Q11 microdeletion, which is found in up to 34% of patients, and up to 65% of patients with MAPCAs are found to have this abnormality.³ Other phenotypic abnormalities with the 22Q11 microdeletion include submucosal cleft palate, abnormal facies, delayed development, and mental retardation. Neonates with trisomy 13 or 18 may have PA/VSD as well, and the prognosis is extremely poor for these children.

Anatomy and Pathophysiology

As in tetralogy of Fallot, PA/VSD is associated with anterior deviation of the infundibular septum, a conoventricular VSD, and the resulting aortic override (Fig. 120-1). The spectrum of pulmonary atresia varies from purely valvular or subvalvular atresia (with intact main and branch pulmonary arteries) to complete absence of central pulmonary arteries. Pulmonary blood flow is dependent on the presence of an aortopulmonary communication, which may exist in the form of a patent ductus arteriosus (PDA), other major nonductal collaterals arising from the descending aorta that connect to the central native pulmonary arteries, or MAPCAs that directly enter the hilum and join the segmental pulmonary arteries. In utero, the pulmonary parenchyma is perfused by branches from the dorsal aorta as well as by the sixth aortic arch, which forms the basis for the central pulmonary arteries. Abnormal development of the central

pulmonary arteries leads to persistence of the dorsal aortic branches, which ultimately develop into MAPCAs.

The lungs may be supplied by the native pulmonary arteries, by MAPCAs, or by both. If confluent central pulmonary arteries are present, the blood supply to the lung may arise from a PDA, a central “ductlike” collateral, or a MAPCA. The behaviors of these three sources of pulmonary blood flow differ in their predisposition to constrict over time, which has implications for the stability of pulmonary blood flow. Whereas MAPCAs or ductlike collaterals might remain patent beyond the neonatal period, the PDA is likely to constrict postnatally because of the presence of prostaglandin-responsive ductal tissue. Although the distinction may be difficult to establish by preoperative imaging studies, the location on the aorta from which the collateral originates is suggestive. A solitary collateral that arises just distal to the left subclavian artery (if left aortic arch) and travels to a central pulmonary confluence is likely to be a PDA, whereas a collateral that arises from any other location off the aorta and supplies a central confluence is termed a ductlike collateral. A vessel that exits the descending aorta and travels directly to the pulmonary parenchyma is likely a MAPCA. There may be heterogeneity in the sources of pulmonary blood flow within any given patient, such that one segment of lung may be supplied by the native pulmonary artery whereas another segment may be supplied by a MAPCA. Some segments may have a dual supply (Fig. 120-2). Patients with confluent central pulmonary arteries that are supplied by a PDA are less likely to have significant MAPCAs, and those with nonconfluent central pulmonary arteries depend on MAPCAs for pulmonary blood flow.

FIGURE 120-2 ■ Variations in aortopulmonary collateral morphology in pulmonary atresia with ventricular septal defect.

FIGURE 120-3 ■ Variations in pulmonary supply from native pulmonary arteries (*hatched gray*) and major aortopulmonary collateral arteries (*solid black*) encountered in patients with pulmonary atresia with ventricular septal defect.

Classification

There is no standard classification system for PA/VSD; however, several have been purported. Most classification schemes focus on the patterns of pulmonary blood flow. The classification system adopted by the Congenital Heart Surgery Nomenclature Project broadly divides pulmonary artery anatomy according to the following: central pulmonary arteries without MAPCAs, confluent central pulmonary arteries and dual supply with MAPCA, nonconfluent or absent central pulmonary arteries with MAPCA.⁴

Another classification scheme divides patients further according to specific patterns of pulmonary artery anatomy that are most commonly encountered (Fig. 120-3):

- I. Valvar pulmonary atresia with a decent-sized main pulmonary artery and confluent central pulmonary arteries. This variant is associated with a PDA and therefore not associated with MAPCAs.
- II. Absent main pulmonary artery with confluent, decent-sized or mildly hypoplastic central pulmonary arteries supplied by a PDA, without MAPCAs.
- III. Confluent central pulmonary arteries with MAPCAs but no PDA.
 - a. Central pulmonary artery z-score > -2.5
 - b. Central pulmonary artery z-score < -2.5

- IV. Nonconfluent or absent central pulmonary arteries with MAPCAs.
- V. Nonconfluent central pulmonary artery with PDA and MAPCAs.

Natural History

The natural history of PA/VSD varies significantly depending on the pulmonary artery morphology. Patients presenting with PA/VSD that has ductal dependent pulmonary blood flow will experience profound fatal cyanosis in the neonatal period as the ductus begins to close. On the other hand, patients with MAPCAs with mild stenosis of collateral vessels and balanced pulmonary blood flow exhibit mild cyanosis and may survive into adolescence or adulthood without repair. Progressive development of ostial stenosis within the collateral leads to progressive cyanosis. Alternatively, excessive pulmonary blood flow from an unrestrictive collateral results in congestive heart failure. The presence of long-standing unrestrictive blood flow within a MAPCA may result in irreversible elevation of pulmonary vascular resistance within that segment. Pulmonary hypertension within a segment of the lung is seen commonly in patients who present at later age. Heterogeneity in pulmonary vascular resistance within a lung segment results in $\dot{V}/\dot{Q}$ mismatch. Without timely intervention, the overall mortality rate is approximately 60% by 30 years of age, with most of the mortality occurring within the first year of life.^{1,5}

FIGURE 120-4 ■ Angiograms demonstrating major aortopulmonary collateral artery to left lung (A) and redundant collateral to left lung also supplied by hypoplastic native pulmonary arteries (B).

Clinical Presentation

The clinical presentation varies according to pulmonary artery morphology. Patients with ductal-dependent pulmonary circulation present with profound cyanosis during the first several weeks of life as the ductus begins to close. Children with progressively restrictive aortopulmonary collaterals may present in childhood with cyanosis, whereas patients with large, unrestrictive collaterals may present with heart failure symptoms such as failure to thrive, tachypnea, or feeding intolerance. Among infants presenting during infancy, 50% present with cyanosis and 25% present with heart failure symptoms.⁵ Rarely, in a child with balanced pulmonary blood flow, symptoms may not manifest until adolescence or adulthood.

Diagnostic Studies

Initial Studies

In the current era, prenatal diagnosis is frequently established by fetal ultrasound and echocardiography by the demonstration of absence of antegrade pulmonary artery blood flow. A neonate presenting with cyanosis following ductal closure may demonstrate hypovascular lung fields by chest radiography, whereas an infant presenting with excessive pulmonary blood flow and congestive heart failure may demonstrate interstitial edema and prominent hilar vessels. A right-sided aortic arch may be demonstrated by the position of the aortic knob by chest x-ray, and the diminutive main pulmonary artery results in an exaggerated sabot shape of the cardiac silhouette. By electrocardiography, rightward deviated QRS axis and evidence of right atrial and ventricular hypertrophy are frequently seen.

Echocardiography is the primary modality for diagnosis of this defect, and it provides a significant portion of the anatomic information needed for initial decision making in neonates and infants. The data to be obtained by echocardiography include location, size, and direction of flow in the ventricular and atrial septal defects; size and confluence of the central pulmonary vessels; and

presence of a PDA or other collaterals. Color flow Doppler may suggest the presence of a collateral arising from the descending aorta, but it is not reliable at delineating the entire course. Retrograde flow in the descending aorta suggests significant pulmonary flow through the collateral or PDA. Coronary artery anatomy should be delineated, particularly to exclude the presence of a left anterior descending coronary artery arising from the right coronary artery, because this impacts surgical management.

Cardiac Catheterization

Cardiac catheterization is indicated in patients with PA/VSD who have nonconfluent or hypoplastic central pulmonary arteries in whom MAPCAs are suspected (Fig. 120-4). The goal of catheterization in these patients is surgical planning by evaluating the anatomy, size, degree of stenosis, and the presence of dual supply from native pulmonary arteries or collaterals. Vascular supply to all segments must be clearly determined. Native pulmonary arteries may require visualization by pulmonary venous wedge injection if no antegrade flow to the native pulmonary arteries can be identified. Relationship of collaterals to the airway (seen best on the lateral view) is important in guiding surgical approach (sternotomy vs. thoracotomy). In older children and adults, measurements of individual pulmonary artery pressures are obtained to determine the risk of development of pulmonary hypertension in high-pressure collaterals. The pulmonary-to-systemic blood flow ratio (Q_p/Q_s) can be estimated by the Fick method if all pulmonary flow arises from collaterals (i.e., if there is no previous right ventricle-to-pulmonary artery [RV-to-PA] conduit). Interventions that may be performed at catheterization include balloon dilation of native pulmonary vessels, stenting of highly restrictive MAPCAs, or coiling of redundant dual-supply collaterals.

Cardiac catheterization is rarely indicated for types I or II PA/VSD with normal-sized central confluent pulmonary arteries demonstrated by echocardiogram, because the risk of collaterals is low and surgical

management is complete repair. Exceptions include patients at high risk for surgical management, in whom catheter-based intervention (stenting of PDA or right ventricular outflow tract [RVOT]) is contemplated.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a useful adjunct to cardiac catheterization in patients with MAPCAs. The advantage of MRI is its ability to image native pulmonary arteries that may not be accessible by cardiac catheterization. It is superior to other imaging modalities at delineating the relationship of MAPCAs to other mediastinal structures (airway, esophagus).⁶ MRI is used to estimate right ventricular volumes and conduit regurgitation fraction in completely repaired patients and guides decision making regarding conduit replacement.

Radionuclide Lung Perfusion Scanning

In patients with stenosis of pulmonary arteries (within collaterals or following unifocalization), decreased blood flow to specific segments of lung may portend irreversible vascular occlusion. Segmental malperfusion detected by lung perfusion scanning can be used to screen patients for the presence of significant stenoses of the native pulmonary arteries or MAPCAs.⁷ A heterogeneous perfusion pattern may indicate that certain segments are under high pressure and others are underperfused. Progressive reduction in segmental lung perfusion prompts cardiac catheterization and intervention to prevent irreversible vascular occlusion.

Medical Treatment

In a neonate with PDA-dependent pulmonary blood flow, prostaglandins are infused at 0.01 to 0.1 $\mu\text{g/kg/min}$ to maintain ductal patency and preserve pulmonary blood flow. Preoperative mechanical ventilation is not necessary and may even be detrimental if it lowers the PVR and increases the left-to-right shunt. Diuretics may be used for patients with heart failure symptoms.

Surgical Treatment

The ultimate goal of the surgical repair strategy is creation of biventricular circulation with unobstructed RV-to-PA continuity and elimination of intracardiac or extracardiac shunts with low resultant right ventricular pressure. To attain this goal, the VSD must be closed and branch and segmental vasculature must be recruited, and vascular caliber must be maximized to minimize pulmonary resistance. Generally, the repair strategy centers on optimizing pulmonary artery recruitment and thus varies depending on native pulmonary artery morphology and collateral supply.

Confluent Central Pulmonary Arteries without Major Aortopulmonary Collateral Arteries

If the central pulmonary arteries are confluent and normal in caliber, a PDA is usually present. Complete repair in

the neonatal period consists of reconstituting RV-to-PA continuity, ligation of the PDA, and VSD closure. In most patients, RV-to-PA continuity is established with a valved conduit (see [Right Ventricle-to-Pulmonary Artery Conduit](#) section). In patients with purely valvular atresia who have a patent main pulmonary artery segment, a transannular patch may be associated with longer freedom from reintervention compared to an RV-to-PA conduit.⁸ However, this approach may be associated with longer postoperative recovery and cyanosis related to a noncompliant right ventricle. Conversion to RV-to-PA conduit may become necessary in a subset of these patients.

Some centers prefer to perform a palliative systemic artery-to-pulmonary artery or RV-to-PA shunt in neonates, followed by complete repair later in infancy.⁹ This strategy minimizes the potential morbidity of neonatal repair and promotes growth of the central pulmonary arteries but places the patient at risk for shunt thrombosis, which can be fatal if the ductus is closed.¹⁰ Shunting as the initial procedure has been identified as a risk factor for early mortality in several retrospective series.^{11,12}

Transcatheter procedures such as radiofrequency perforation or ductal stenting are palliative alternatives to complete repair. Radiofrequency perforation of membrane-like atresia of the pulmonary valve combined with balloon dilation or stenting of the outflow tract can delay complete repair for 2 to 4 months.¹³ Stenting of PDA maintains stable blood flow in a neonate with confluent central pulmonary arteries following discontinuation of prostaglandins and promotes vascular growth.¹⁴ Stent implantation is hampered by tortuosity of the PDA. Stent migration, embolization, and restenosis have been reported.^{12,15} Given the low mortality of neonatal complete repair, palliation may be most appropriate for high-risk patients (genetic abnormalities, intracranial hemorrhage, pulmonary disease).

Hypoplastic Central Pulmonary Arteries with Major Aortopulmonary Collateral Arteries

In patients with diminutive central pulmonary arteries, simple VSD closure and RV-to-PA conduit would lead to elevated right ventricular pressure because of small vascular caliber, segmental vascular discontinuity, and accessory collateral supply. Delineation of branch pulmonary artery anatomy and collateral supply by cardiac catheterization is imperative in guiding the reconstructive strategy. If native central and branch pulmonary arteries are simply diminutive yet demonstrate continuity with all lung segments, initial intervention to promote growth of the central native pulmonary artery can be followed by eventual complete repair. Central pulmonary artery growth in this setting is stimulated by providing antegrade blood flow via either an aortopulmonary shunt or a restrictive RV-to-PA conduit and elimination of redundant collateral supply. There are several advantages of an RV-to-PA conduit over aortopulmonary shunt for this indication. Transcatheter access to the branch pulmonary arteries for sequential dilation is much easier through an RV-to-PA conduit than through an aortopulmonary shunt. Particularly in older infants, the use of an RV-to-PA

conduit may be superior to an aortopulmonary shunt in promoting growth of native pulmonary arteries.¹⁶

Aortopulmonary collaterals that are discontinuous with central pulmonary arteries may provide the sole supply to significant segments of lung. Recruitment of these collaterals into the central pulmonary artery segment is essential to ensure low right ventricular pressures and optimize V/Q matching. Unifocalization refers to the technique by which collaterals are disconnected from the aorta and anastomosed to a common confluence that can receive blood supply from a stable source—usually an RV-to-PA conduit or aortopulmonary shunt. If the collaterals are accessible from an anterior approach, unifocalization at the time of shunting or RV-to-PA conduit placement is performed by end-to-side anastomosis.

Anastomotic stenosis at the site of unifocalization requires transcatheter intervention to avoid loss of segmental blood flow in approximately 50% of patients at 5 years.¹⁷ High rate of collateral occlusion or stenosis has prompted some groups to pursue rehabilitation of hypoplastic native pulmonary arteries by a neonatal shunting regimen alone, without collateral unifocalization in select patients with diminutive central pulmonary arteries and MAPCAs.^{18,19}

Once growth of the central and branch pulmonary arteries is achieved, closure of the VSD with an unrestricted RV-to-PA conduit can be performed. Nuances regarding the timing and technical aspects of VSD closure are discussed later in this chapter (see [Closure of Ventricular Septal Defect](#) section).

Absent Central Pulmonary Arteries with Major Aortopulmonary Collateral Arteries

If central pulmonary arteries are absent, or if significant segments of pulmonary blood flow are supplied solely by MAPCAs, the repair strategy mandates unifocalization of branch pulmonary arteries and reconstruction of central pulmonary arteries prior to consideration of complete repair. Many of these patients demonstrate stable balanced pulmonary blood flow for a period of time as the collaterals are restrictive enough to limit pulmonary blood flow. Thus, the initial intervention may be delayed for several months. With time, however, segmental pulmonary hypoperfusion or hyperperfusion may lead to cyanosis or segmental pulmonary vascular disease, respectively. Close observation is imperative, and repair is recommended if significant imbalance of circulation develops.

Cardiac catheterization is essential to delineate anatomy as well as perform initial palliative interventions. Collaterals can be coil occluded if they provide redundant blood flow to segments also supplied by native pulmonary arteries. This reduces competitive flow and prevents overcirculation. Highly restrictive collaterals that are essential to maintaining pulmonary blood flow are stented at their proximal portions (the segment most likely to develop stenosis) until unifocalization can be performed.

Although most patients with PA/VSD and MAPCAs undergo initial surgical intervention between 3 and 6 months of age, earlier surgery may be necessary in certain

patients with (1) heart failure related to unrestrictive collaterals, (2) a ductal-dependent collateral that is prone to early occlusion, and (3) hemitruncus to one lung and contralateral MAPCAs.²⁰

The operative approach to and timing of unifocalization of collaterals, RV-to-PA conduit, and VSD closure hinge on the morphology of collaterals. Unifocalization involves identification and recruitment of branch pulmonary arteries into a centrally located confluence to which a conduit may eventually be sewn. Successful unifocalization requires careful review of preoperative studies (catheterization and MRI) to delineate the size, course, and location of stenoses within each collateral. Important considerations related to the unifocalization procedure include approach (sternotomy vs. thoracotomy), timing (single operation or multiple-stage procedures), and the source of blood flow to the unifocalized vessels (aortopulmonary shunt vs. RV-to-PA conduit).

Decision regarding timing of closure of the VSD depends on the anticipated or measured resistance of unifocalized vessels. If all segments of pulmonary vasculature are satisfactorily unifocalized and resistance is low, then VSD closure may be performed at the time of unifocalization (one-stage complete repair). If high resistance is anticipated or encountered, then unifocalization with a shunt or RV-to-PA conduit to promote growth of the vasculature followed by subsequent VSD closure is preferable.

Single-Stage Unifocalization and Complete Repair

A patient with MAPCAs that are large in caliber and easily accessible from a sternotomy approach (course anterior to the bronchus) may be a candidate for *single-stage unifocalization*, during which all significant collaterals are detached from the aorta and implanted into a central confluence during a single operation ([Fig. 120-5](#)). Following single-stage unifocalization, if the vascular bed is deemed suitable to handle a full cardiac output, then *single-stage complete repair* (VSD closure with an unrestrictive valved RV-to-PA conduit) is feasible. However, if high vascular resistance is anticipated or encountered following unifocalization, options include (1) fenestrated VSD closure with an RV-to-PA conduit or (2) restrictive source of pulmonary blood flow (aortopulmonary shunt or RV-to-PA conduit), leaving the VSD open. These two options promote growth of unifocalized vessels and allow access for subsequent catheter-based interventions. Complete repair with an RV-to-PA conduit and VSD closure is performed once satisfactory pulmonary vascular bed is achieved.

Because single-stage complete repair depends on morphology of the pulmonary vascular bed, several scoring systems based on preoperative imaging (MRI, CT scan, or angiography) have been developed to predict likelihood of successful VSD closure at the time of single-stage unifocalization. The number of pulmonary vascular segments to be recruited has been used to predict low right ventricular pressures following VSD closure.²¹ The total neopulmonary arterial index is the sum of the cross-sectional areas of the right and left pulmonary arteries as

FIGURE 120-5 ■ Single-stage reconstruction of pulmonary atresia with ventricular septal defect with unifocalization, ventricular septal defect closure, and right ventricle-to-pulmonary artery conduit.

well as all collateral vessels, normalized to body surface area, and an index greater than $150 \text{ mm}^2/\text{m}^2$ has been associated with successful VSD closure at the time of unifocalization.²² Functional assessment of vascular resistance following single-stage unifocalization may also be used to guide intraoperative decisions regarding VSD closure.²³ Intraoperative determination of vascular resistance by measuring the pressure generated on perfusing the unifocalized pulmonary arteries with constant flow perfusate has been shown to predict postoperative right ventricular pressures.²⁴

The advantages of the single-stage unifocalization or complete repair include avoidance of bilateral thoracotomies, avoidance of multiple operations, and immediate antegrade access for transcatheter intervention on the unifocalized pulmonary vasculature. The major disadvantage of this approach is the risk of progressive stenosis of the unifocalized collateral. A typical MAPCA consists of a proximal muscular segment that resembles a systemic arterial vessel and a distal thin-walled segment that resembles a pulmonary artery. The proximal muscular segment is susceptible to progressive stenosis. Although it is preferable to perform unifocalization anastomoses to the distal pulmonary artery-like segment to reduce the risk of restenosis, this is not always feasible through a sternotomy approach. Additional disadvantages include the long duration of cardiopulmonary bypass and difficult access to the posteriorly located collaterals.

Multiple-Stage Repair Strategy

A patient with long-segment stenoses of collateral vessels or patency of only hilar vessels requires a thoracotomy approach to provide adequate visualization of the hilar

pulmonary vessels, which are not accessible through a sternotomy approach. Generally, staged bilateral thoracotomies are performed with eventual complete repair once adequate recruitment of branch pulmonary arteries and caliber of central pulmonary arteries has been achieved. At each thoracotomy procedure, segmental pulmonary vessels are brought into continuity with a conduit (typically a homograft) and provided a source of blood flow, generally via a polytetrafluoroethylene (PTFE) shunt from the ipsilateral subclavian artery.

Catheterization within several months of each thoracotomy allows delineation of resultant pulmonary artery morphology and dilation of stenoses. MRI provides not only anatomic but also functional information to aid surgical decision making in patients with multiple sources of pulmonary blood flow.²⁵ Once vascular segments to both lungs have been satisfactorily recruited and rehabilitated, complete repair via sternotomy is performed for placement of an RV-to-PA conduit (connecting to the conduits placed at previous thoracotomy) and closure of the VSD (+/- fenestration).

Under rare circumstances, transverse thoracosternotomy or bilateral thoracotomies for unifocalization followed by sternotomy for an RV-to-PA conduit and VSD closure at a single procedure (modified single-stage unifocalization and complete repair) may be performed.²⁶ The disadvantage of this approach includes longer operative time and increased risk of bleeding at the distal pulmonary anastomoses.

Transplantation

Lung or heart-lung transplantation has been applied selectively for certain patients, generally adolescents or adults, with irreversible pulmonary hypertension. For patients with normal ventricular function, lung transplantation, with or without cardiac repair (VSD closure or conduit change), may be performed. Heart-lung transplantation must be considered for patients with myocardial dysfunction or complex intracardiac defects.²⁷

Technical Considerations

Cardiopulmonary Bypass Strategy

Cardiopulmonary bypass is required for procedures involving VSD closure or RV-to-PA conduit placement. Thus, single-stage unifocalization with an RV-to-PA conduit via a sternotomy approach requires cardiopulmonary bypass, whereas unifocalization to a systemic shunt through a thoracotomy does not. The bypass strategy must be tailored to patients with MAPCAs because runoff into the pulmonary circulation can result in systemic hypoperfusion as well as poor visualization during intracardiac repair or pulmonary artery reconstruction as a result of flooding of the field with collateral blood flow. Control of all accessible collaterals following initiation of bypass is recommended, and higher flows (cardiac index of up to $4.0 \text{ liter}/\text{min}/\text{m}^2$ if necessary) are used to maintain systemic perfusion. Hypothermia reduces metabolic demand and provides protection of end organs in situations of reduced systemic perfusion. It allows the surgeon

to reduce or briefly interrupt bypass flow to improve visualization of the surgical field during critical portions of the operation. When appropriate, maintenance of cardiac contractions and pulsatile flow (by not completely emptying the heart) during bypass may provide superior systemic perfusion in the presence of collateral runoff. Cardioplegic arrest is required for repair of VSD but can also be used during placement of the RV-to-PA conduit.

Closure of Ventricular Septal Defect

The VSD may be closed with Dacron, PTFE, or pericardial patch material. The decision to close the VSD depends on the preoperative and intraoperative assessment of the pulmonary runoff. Failure to close the VSD in the setting of unobstructed right ventricular outflow leads to significant left-to-right shunting and congestive heart failure. In contrast, closure of the VSD in the presence of inadequate pulmonary artery bed results in right ventricular hypertension and low cardiac output. Fenestrated VSD closure is performed in equivocal or borderline cases. Use of PTFE or tissue material for patch closure (in contrast to Dacron) facilitates catheter-based enlargement of fenestration should elevated right ventricular pressures be encountered postoperatively. Fenestration within the VSD patch may spontaneously close over time or may be closed in the catheterization laboratory.

The conduction system is generally remote from the edges of the VSD in a typical patient with PA/VSD. However, extension of the VSD into the membranous septum may place the conduction system at risk for injury at its posterior and inferior margin. Acute angulation of the VSD contour at the ventricular-infundibular fold (rightward margin just beneath the conal septum) may lead to residual patch margin VSD following closure, and special care must be taken when placing sutures at this location.

Right Ventricle-to-Pulmonary Artery Conduit

An RV-to-PA conduit can be sewn either to confluent central native pulmonary arteries or to unifocalized pulmonary vascular segments. The type of conduit chosen depends on the size of the child, caliber of the distal pulmonary vascular bed, and status of the VSD. If the VSD is left unrestrictive and the purpose of the RV-to-PA conduit is to promote vascular growth, then a nonvalved PTFE graft or restrictive homograft is selected. Following complete repair, an unrestrictive, valved conduit (homograft, xenograft) is preferred to minimize right ventricular pressure and volume load.

Details regarding coronary artery anatomy should be obtained prior to incising the infundibulum. The course of the left anterior descending coronary artery may be marked prior to cardioplegic arrest so that the location of ventriculotomy can be performed a sufficient distance from this structure. Presence of the left anterior descending artery arising from the right coronary artery (either as dual or sole supply) must be excluded, as this vessel frequently crosses the infundibulum. If anomalous origin

is identified, the location of the right ventriculotomy must be modified to avoid injury to this vessel.

Transannular Patch

In patients with pulmonary valvular atresia, the presence of an imperforate membrane at the valve level is the primary abnormality. Infundibular muscular stenosis may also be present, and the main pulmonary artery is variably hypoplastic. This anatomy is amenable to augmentation of the RVOT with a transannular patch that extends from the infundibulum to the bifurcation of main pulmonary artery. This approach reduces the need for RVOT reoperation but creates pulmonary regurgitation. Use of a monocusp transannular patch may prevent early pulmonary regurgitation with this approach.^{28,29}

Complete division of the parietal muscle bands at the time of transannular patching reduces the risk of recurrent RVOT obstruction. Presence of anomalous left anterior descending artery crossing the RVOT is not an absolute contraindication to transannular patching but may limit the extent of the ventriculotomy. An alternative approach with an RV-to-PA conduit should be considered in these patients.

Maintenance of Patent Foramen Ovale

Following complete repair of PA/VSD, low right ventricular compliance related to the ventriculotomy and hypertrophic ventricle leads to elevated right atrial pressures and low cardiac output, which manifests as hepatic congestion, anasarca, and renal insufficiency. A small atrial septal defect between 3 and 4 mm (in an infant) prevents right atrial hypertension and preserves cardiac output by allowing right-to-left shunting at the atrial level. Closure of the patent foramen ovale (PFO) at the time of complete repair has been associated with increased length of stay and hospital death.³⁰ Right-to-left shunting results in systemic oxygen desaturation, which is well tolerated in neonates and infants and improves as right ventricular compliance normalizes. Balloon dilation of the PFO may be performed in the catheterization laboratory if elevated atrial pressures are encountered postoperatively. Closure of residual intracardiac shunts may be performed at the time of conduit replacement or cardiac catheterization.

Aortopulmonary Shunting

Aortopulmonary shunts can be used after unifocalization of MAPCAs or as initial palliation in patients with diminutive but confluent central pulmonary arteries. The PDA or other major collateral supplying the pulmonary artery is generally ligated at the time of shunting, although several centers have advocated for maintaining PDA patency.³¹ These shunts are constructed with PTFE tube grafts or direct anastomosis and promote growth of pulmonary artery segments prior to eventual complete repair. The most common form of aortopulmonary shunt is the modified Blalock-Taussig shunt (subclavian artery-to-pulmonary artery PTFE graft), but other forms include the central PTFE shunt, Waterston shunt

(ascending aorta-to-pulmonary artery graft) and Mel-bourne shunt (direct end-to-side anastomosis of pulmonary artery to ascending aorta).³²

The modified Blalock-Taussig shunt may be performed through a sternotomy or thoracotomy incision. The size of shunt used depends on the size of the child and morphology of the pulmonary artery. A 3.5-mm shunt supplies adequate flow to both lungs in a neonate, whereas 3.5- to 4-mm shunt is used to provide flow to each vascular bed for an infant undergoing thoracotomy for staged unifocalization. Thrombosis prophylaxis with the platelet inhibitor aspirin is the standard of care; the addition of clopidogrel may or may not provide further advantage.^{33,34} The shunt is divided once continuity is established between the right ventricle and the unifocalized confluence.

Single-Stage Unifocalization

Through a sternotomy incision, MAPCAs, as they arise from the descending aorta, are identified in the posterior mediastinum by dissecting the infracarinal and paratracheal space. On institution of cardiopulmonary bypass, all MAPCAs must be controlled to avoid significant runoff into the pulmonary vasculature. MAPCAs are identified, divided, and incorporated into a central confluence. Functional assessment of pulmonary resistance may be performed at this time to guide the decision regarding VSD closure. One-stage complete repair entails VSD closure and an RV-to-PA conduit at the time of unifocalization. After cardioplegic arrest, an infundibular right ventriculotomy is performed, through which the VSD is closed with or without a fenestration. If adequacy of the pulmonary vasculature is questionable, it is safe to leave a fenestration because suprasystemic right ventricular pressures are not as well tolerated as a small residual left-to-right shunt. The unifocalized confluence is sewn to the distal end of the conduit. The proximal portion of the conduit is anastomosed to the right ventriculotomy incision, generally with a hood of pericardium to avoid distortion and tension at the proximal anastomosis.

Multiple-Stage Unifocalization

The decision regarding order of MAPCA unifocalization (right vs. left vessels) depends on the degree of compromise of vascular supply. The side with the most severe MAPCA restrictions is generally unifocalized first because these are at highest risk for progressive occlusion, and ligation of these collaterals at the time of the procedure is less likely to result in significant systemic desaturation. Through a thoracotomy, all MAPCAs are identified and ligated proximally. The distal pulmonary vessels are exposed and correlated with preoperative images to ensure that all essential vessels are unifocalized. Hilar dissection may be necessary to expose segmental vessels. A vascular graft (homograft, pericardial tube, or prosthetic) is anastomosed to all essential branch vessels. The proximal end of this vascular graft is placed anteriorly in the pleural space to facilitate eventual access through sternotomy at the time of complete repair. A shunt is

placed between the subclavian artery and the conduit to provide antegrade pulmonary blood flow. This process is repeated in the contralateral thoracic cavity during a separate operation, although staged unifocalization at a single procedure has been performed.

Postoperative Assessment and Management

The success of repair for PA/VSD depends primarily on the anatomic result of pulmonary artery unifocalization or reconstruction. If a low-impedance pulmonary vascular system is achieved, closure of VSD may be performed with low right ventricular pressures. Right ventricular pressures of less than two-thirds systemic are generally felt to be well tolerated long term, whereas suprasystemic pressures are poorly tolerated in the short or long term.

Right ventricular pressure can be assessed following closure of the VSD in the operating room by direct measurement after separation from bypass. Right ventricular pressures greater than 80% of systemic arterial pressures often indicate inadequate pulmonary vascular bed. Because elevated right ventricular pressures are poorly tolerated long term, fenestration of the VSD patch must be performed if suprasystemic right ventricular pressures are encountered.

Postoperative echocardiography and lung perfusion scanning are noninvasive modalities used to follow up on the results of repair and guide further management. Lung perfusion scanning detects perfusion defects within various pulmonary segments and indicates pulmonary artery or MAPCA occlusion. Echocardiography is used to assess right ventricular pressures, intracardiac shunts, RVOT obstruction, and conduit regurgitation. The direction of flow across any residual VSD helps determine the degree of RVOT obstruction in patients undergoing staged palliation. The presence of primarily right-to-left shunting indicates inadequate pulmonary bed and warrants further pulmonary vascular rehabilitation or recruitment prior to VSD closure.

If progressive vascular disease is suspected by echocardiogram or perfusion scanning, cardiac catheterization is indicated. If multistage repair strategy has been undertaken, catheterization is performed before each stage. At cardiac catheterization, pulmonary artery pressures and Qp/Qs are measured. The Qp/Qs measurement by the Fick method may be inaccurate if dual sources of blood supply (MAPCA and right ventricle) are present. Cardiac catheterization also reveals pulmonary artery arborization pattern and size and allows intervention for pulmonary vascular rehabilitation. Transcatheter closure of fenestration in the VSD patch or PFO is possible if favorable conditions are present.

Results

Hospital survival for the initial procedures is greater than 90% in most series. Risk factors for poor outcome (mortality, reoperation, or failure of repair) following complete repair of PA/VSD and MAPCAs that have been identified include pulmonary artery morphology, 22Q11 microdeletion, and older age at palliation.^{3,35,36}

Long-term results of repair for patients with hypoplastic or absent central pulmonary artery with MAPCAs are highly variable.^{17,18,20,21,37-40} Approximately 80% of infants presenting with this anatomy may be amenable to single-stage unifocalization, and up to 50% of these patients are candidates for simultaneous complete repair. The operative mortality rate for single-stage unifocalization ranges from 2% to 15%. Survival rate at 5 years with either single- or multiple-stage unifocalization is 85% with eventual complete repair achieved in 70% to 90% of patients. In patients who undergo complete repair, elevated right ventricular pressures may be encountered in up to 50% of patients. Mean right ventricular to left ventricular pressure ratio reported in the literature at mid-term follow-up ranges from 0.4 to 0.6.^{35,39} More than half of septated patients will require catheter intervention within 10 years following complete repair.⁴¹ Reoperation following complete repair for conduit replacement is inevitable when complete repair is performed in neonates and infants.

Conclusion

PA/VSD encompasses a wide spectrum of lesions that are distinguished primarily by the pulmonary vascular morphology. The preoperative evaluation must delineate the source, size, and adequacy of pulmonary blood flow. Therapeutic strategy and timing are tailored according to the pulmonary vascular morphology, with the ultimate goal being establishment of a low-resistance pulmonary vascular bed, RV-to-PA continuity, elimination of intracardiac and extracardiac shunts, and resultant low right ventricular pressure. Surgical options include single-stage complete repair or staged palliation followed by complete repair, depending on the pulmonary artery morphology. Following complete repair, reintervention for pulmonary artery balloon dilation or conduit replacement is common. Long-term outcomes are dependent on the morphology of the pulmonary vasculature and the surgeon's ability to recruit a low-resistance vascular bed.

RIGHT VENTRICLE-TO-PULMONARY ARTERY CONDUITS

Introduction

Prosthetic valves and conduits are used to establish continuity between the pulmonary ventricle (morphologic right ventricle or left ventricle) and the pulmonary arteries as a part of complete repair or palliative reconstruction. Examples of defects with pulmonary obstruction that may require conduit placement include tetralogy of Fallot, pulmonary atresia (with intact ventricular septum or VSD), truncus arteriosus, D-transposition of the great arteries (TGA)/VSD or double-outlet right ventricle with pulmonary stenosis (as a part of Rastelli or Nikaidoh operations), and L-TGA/VSD with pulmonary stenosis. Conduits are also used concomitantly during procedures for left ventricular outflow tract (LVOT) obstruction that

use the normal native pulmonary valve for the LVOT reconstruction. The Ross procedure, in which the pulmonary autograft is harvested and placed into the LVOT position, uses a conduit to reestablish RV-to-PA continuity. Similarly, the operation described by Yasui and colleagues^{41a} for repair of interrupted aortic arch/VSD/severe LVOT obstruction uses the normal pulmonary valve for LVOT reconstruction and requires placement of an RV-to-PA conduit.

Choice of Conduit

Options for ventricle-to-pulmonary artery continuity include synthetic, allograft, xenograft, and autologous tissue conduits. Unfortunately, none of the currently available conduits is ideal, and each is associated with specific advantages and disadvantages. None of the currently available conduits demonstrates growth potential, and conduit stenosis develops as the child grows. Factors to consider in the choice of a conduit include the pulmonary vascular resistance, age and size of the patient, and nature of the concomitant operation (complete repair versus palliation). For example, in the presence of elevated pulmonary vascular resistance, placement of a valved conduit (as opposed to nonvalved conduit) may be preferred to mitigate the effects of pulmonary regurgitation. Age and size of the patient are important because each type of conduit has a specific size limitation (Table 120-1). The type of operation influences the type and size of conduit to be implanted. Thus, if a conduit is required as a part of a palliative operation in which the VSD is left open, a restrictive conduit may be desirable to prevent excessive pulmonary blood flow. If reoperation is planned within a short time interval as a part of staged repair strategy, implantation of a low-cost but less durable conduit may be acceptable.

Allograft

Cryopreserved aortic and pulmonary allografts (or homografts) may be used for ventricle-to-pulmonary artery reconstruction. Advantages of allografts include availability in a wide range of sizes and favorable handling characteristics during implantation. Bifurcating pulmonary grafts or aortic branch vessels can be directly anastomosed to branch pulmonary arteries in the absence of adequate central pulmonary arteries. Major disadvantages include limited supply of the smaller sizes necessary for neonatal repair, the limited shelf life of each allograft (approximately 2 years), and high cost.

Choice of allograft characteristics and size depend on the age of patient and operative indication. For infants and small children who undergo conduit placement, use of conduit other than pulmonary allograft (synthetic, porcine xenografts, aortic homograft) has been shown to be a predictor of early reintervention, suggesting superiority of the pulmonary allograft for RVOT reconstruction.⁴²⁻⁴⁶ Several studies have demonstrated superior longevity of pulmonary allografts compared with aortic allografts, partly because of the accelerated calcification seen in the latter.^{42,45,47,48} However, aortic

TABLE 120-1 Conduit Choices for Patients Based on Age

Conduit Type	Sizes Available	Typical Patient Age Range	Commercial Name (U.S. Manufacturers)
Allograft			
Aortic	6-25 mm	All ages	CryoLife, LifeNet
Pulmonary	8-29 mm	All ages	CryoLife, LifeNet
Xenograft

PTFE Tube Graft			
Nonvalved + implanted	>3 mm	<12 mo	Gore-Tex (Gore)
bioprosthetic valve	20-24 mm	>5 yr	Impra (Bard) Advanta (Atrium)

PTFE, Polytetrafluoroethylene.

homograft is chosen if elevated pulmonary artery pressures are anticipated (palliative conduit following unifocalization), as pulmonary allografts are associated with an increased risk of pseudoaneurysm formation in this setting.^{49,50} The choice of size for a neonate may be influenced by limited availability of small-sized conduits. Modification of an allograft by excision of one leaflet and creation of a smaller “bicuspid” allograft allows use of larger-sized allografts in smaller patients when the appropriate-sized smaller allografts are unavailable.⁵¹ The practice of implanting an oversized allograft into neonates and small children to improve conduit longevity may be associated with early development of conduit regurgitation in children.^{52,53}

Whereas short-term competence of the homograft valve is acceptable, long-term freedom from regurgitation and stenosis is highly variable. Freedom from reintervention rates reported in the literature range widely from 30% to over 80% at 10 years.^{8,44,48,54,55}

Smaller conduit size, or younger age at operation, has been consistently shown in multiple series to be a risk factor for allograft conduit failure with freedom from reoperation at 10 years being less than 50% for homografts less than 19 mm in diameter.⁵⁴ In adolescents, freedom from valvar dysfunction and conduit reintervention at 10 years is approximately 50% and 70%, respectively.⁵⁶ Other risk factors include use of aortic homografts, residual branch pulmonary artery stenosis, ABO or HLA mismatch, and non-Ross operation (particularly operation for truncus arteriosus).^{48,52,57,58} The reason for the discrepancy in durability between Ross and non-Ross patients is unclear but may be related to orthotopic position of the conduit in the former; it is placed more

anteriorly in Rastelli, Yasui, and truncus repairs, which may predispose to compression from the sternum.

Xenograft

Currently available xenograft conduits include bovine jugular vein and porcine aortic root. Advantages of xenograft conduits include abundant supply, low cost, wide range of sizes, and favorable suturing characteristics. The list of commercially available xenograft conduits and size ranges are listed in Table 120-1. Choice of xenograft conduit depends primarily on size and age of patient.

An alternative to allograft in a neonate or infant is the Medtronic Contegra graft, obtained from bovine jugular vein with similar short-term durability between Contegra and pulmonary allografts.^{46,55,57,59} Although short-term durability is acceptable, long-term data are highly variable. Freedom from reintervention ranges from 66% at 3 years to 90% at 7 years.^{57,59-61} Young age at implantation is a risk factor for reintervention and distal conduit stenosis.⁶² In patients with elevated right ventricular pressure or pulmonary hypertension, the Contegra has been associated with graft dilation and decreased durability, raising concern for its use in these patients.^{60,62,63} Surgical implantation of the externally stented bovine jugular vein graft (Melody valve) may limit graft dilation and improve long-term durability.

The porcine aortic root has been used for RVOT reconstruction in older children and adults and is available in sizes ranging from 19 to 29 mm.⁶⁴ These grafts appear to have excellent durability at short-term follow-up, but long-term data are still lacking.^{65,66} This is

an alternative to allograft or synthetic conduit in adolescents and adults.

Autologous Tissue

Autologous pericardium can be fashioned into a valved or valveless conduit and used for RV-to-PA reconstruction.⁶⁷ Monocusp and bicuspid valved conduits have been constructed by sewing autologous pericardial leaflets within a tubular pericardial conduit. Although there have been a few reports describing acceptable durability and even increase in the size of some conduits over time in certain cases, experience with this technique is limited.⁶⁸ Smaller conduit size is associated with increased risk of failure and limits its use in neonatal applications. Lack of access to commercially available conduits (in developing countries) may be an indication for its use.

Synthetic Conduits

Nonvalved. Valveless conduits are used in several settings. A palliative synthetic tube graft from an RV-to-PA conduit may be used in patients with PA/VSD and confluent but hypoplastic central pulmonary arteries in whom pulmonary artery growth is desired. In these patients, the VSD is left open and exposes the pulmonary arteries to elevated pressure. Nonvalved PTFE tube grafts are also used for the RV-to-PA conduit in the stage 1 reconstruction of hypoplastic left heart syndrome. Transmural insertion of a ring-reinforced RV-to-PA PTFE conduit reduces the risk of proximal obstruction compared with epicardial suture technique.⁶⁹ In patients undergoing complete repair with VSD closure, selective use of nonvalved conduits is acceptable but should be avoided in patients with elevated pulmonary vascular resistance, unrepaired tricuspid valve regurgitation, or right ventricular failure.^{70,71}

Valved. Composite conduits made of polyester or PTFE tube grafts with bioprosthetic or mechanical valves are available commercially or can be assembled at the time of the operation (see Table 120-1). Manually constructed composite conduits use a low profile valve secured within the synthetic conduit. Bioprosthetic valves are almost exclusively used because anticoagulation is necessary for mechanical valves, and transcatheter valve replacement is feasible only for the bioprosthetic valves.⁷² Advantages of the synthetic valved conduits include excellent longevity and virtually unlimited shelf life, which makes them readily available. The enclosed bioprosthetic valves have a rigid annulus that is resistant to distortion or compression by external structures (sternum).

A major disadvantage of composite polyester conduits less than 19 mm is accelerated stenosis compared with homografts, which has limited their application in neonates and infants.^{61,73,74} Manually constructed conduits are limited by size availability (the smallest bioprosthetic valve is 19 mm) and are commonly used for replacement of obstructed conduits in older children and young adults. Unlike tissue conduits, these conduits are not amenable to catheter-based enlargement if a child were to outgrow the conduit; thus, implantation of a graft between 24 and

28 mm is optimal. Previous studies suggested inferior durability of these conduits compared with allografts, but recent studies have demonstrated freedom from reintervention of greater than 90% at 5 years.⁷⁵⁻⁷⁸ For larger-sized conduits (>19 mm), durability of porcine-valved polyester or PTFE conduit appears to be equivalent, and perhaps superior, to that of allografts.^{56,71,79,80}

Results

Short- and long-term mortality rates following implantation of an RV-to-PA conduit depend primarily on the underlying cardiac diagnosis and hemodynamic result of the operation. In most recent series, the hospital mortality rate among patients who underwent RV-to-PA conduit implantation has ranged from 1% to 10%, depending on the complexity of the underlying cardiac disease.⁷¹ Risk factors for late mortality have included older age at primary operation and elevated right ventricular to left ventricular pressure ratio.⁶⁰ Conduit freedom from reintervention (surgical or catheter-based) varies significantly depending on conduit or patient type. The strongest risk factor for early reintervention in most of these series has been younger age at operation or use of smaller-sized conduits.⁸¹

Conduit Replacement or Reconstruction

Conduit failure may present in the form of either obstruction or valvular incompetence. The decision to intervene on a conduit hinges on the deleterious effects of conduit failure on right ventricular function. Intervention on the conduit may come in the form of catheter-based balloon dilation and stenting for conduit stenosis or endovascular implantation of pulmonary valve for conduit regurgitation. Surgical reconstruction includes patch augmentation of stenotic conduit and implantation of a prosthetic valve within the in situ conduit. Conduit replacement refers to removal of the conduit and the insertion of a new conduit.

Although there are no established guidelines for conduit replacement, common indications for conduit reintervention include symptoms of right heart failure as well as evidence of right ventricular deterioration in an asymptomatic patient. In the presence of conduit stenosis, the development of right ventricular hypertension (>3/4 systemic) or right ventricular dysfunction should prompt consideration of intervention. Isolated conduit regurgitation, even if severe, can be well tolerated for many years. Data regarding indications for PVR following transannular patch repair of tetralogy of Fallot have been extrapolated to guide management of conduit dysfunction.⁸² Symptoms of exercise intolerance, peripheral edema, and arrhythmias are considered indications for surgery. In an asymptomatic patient, right ventricular dilation (>150 mL/m²), progressive tricuspid regurgitation, QRS prolongation, and ventricular dysfunction are relative indications.⁸²⁻⁸⁵

Frequently, catheter-based intervention is successful at relieving conduit obstruction. Greater than 90% of patients presenting with conduit stenosis are amenable to such intervention, and an immediate reduction in right

ventricular pressures by approximately 20% can be expected.^{86,87} Although conduit stenting has been shown to delay the need for surgical intervention, smaller conduit sizes (less than 10 mm), use of a homograft conduit, and younger age are associated with shorter freedom from surgery.⁸⁷ Experience with percutaneous transcatheter implantation of Melody valve within previous RVOT conduit is encouraging. Freedom from valvular dysfunction of 93% at 1 year and greater than 70% at 5 years has been demonstrated.^{88,89} Use of this transcatheter valve has increased dramatically over the past 5 years but is limited to patients in whom conduit internal diameter can be expanded to 22 mm, which is the optimal external diameter of the Melody valve. Patients with conduit internal diameter greater than 24 mm are not candidates, because the valve cannot be sealed within the RVOT.

Options for surgical intervention on dysfunctional conduit include replacement and reconstruction. Conduit reconstruction is performed by incising the anterior portion of the conduit, implantation of a prosthetic valve, and placement of a prosthetic roof over the remaining fibrous bed of the explanted conduit. This type of reconstruction is a durable alternative to conduit replacement, with 90% freedom from reoperation at 10 years.⁹⁰ Alternatively, conduit replacement may be performed with an appropriately sized graft.

Increasing experience with transcatheter valves has prompted interest in hybrid techniques for valve insertion in patients with high surgical risk but enlarged RVOT (hence not candidates for transcatheter replacement). Techniques include transapical or transfemoral delivery with fixation in the pulmonary artery without the use of cardiopulmonary bypass.

Technical Considerations

It is important to evaluate the position of the conduit relative to the sternum on the available preoperative imaging (lateral chest x-ray, catheterization, MRI, or CT scan).⁹¹ Fusion of calcified conduit to the posterior table of the sternum may warrant cannulation of the femoral vessels and institution of cardiopulmonary bypass prior to sternal entry.^{91,92} The presence of residual intracardiac shunts (PFO or VSD) should be determined preoperatively because the decision to close any residual defects guides the intraoperative cannulation and bypass strategy. Air entrainment during cardiopulmonary bypass can be associated with stroke, and the use of cardioplegic arrest or fibrillation with left ventricular venting is preferable to empty, beating heart.

If atrial or ventricular arrhythmias are present, preoperative evaluation by electrophysiologic mapping and ablation are appropriate. Surgical cryoablation is recommended for patients with atrial or monomorphic ventricular arrhythmias in whom preoperative ablation is not performed or is unsuccessful.⁹³

Results

The operative mortality rate of conduit replacement or reconstruction is 5% to 10%, and long-term results

(mortality, freedom from reoperation) after reoperation for conduit replacement or reconstruction are equivalent to those of primary conduit placement.^{58,94}

TRUNCUS ARTERIOSUS

Truncus arteriosus is a relatively rare congenital heart defect with a single vascular trunk arising from the heart, giving origin to the true pulmonary arteries, aorta, coronary arteries, and brachiocephalic vessels. The lesion accounts for approximately 0.4% to 4.0% of all congenital heart lesions.¹⁻³ Truncus arteriosus was first described by Wilson⁴ in 1798. In 1942, Lev and Saphir⁵ defined the anatomy currently associated with truncus arteriosus.

Embryology

During the fifth week of gestation, paired lateral ridges appear in the cephalic portion of the truncus. These truncal swellings ultimately form the aortopulmonary septum. The right superior truncus swelling, located on the right superior wall of the truncus, grows distally and leftward, whereas the left inferior truncus swelling, located on the left inferior wall, moves distally and rightward. The opposing movements of the swellings as they grow toward the aortic sac result in the spiraling of the aortopulmonary septum. The most proximal portions

of the swellings form parts of the infundibular or conal septum. Hence, variable deficiency of these truncal swellings results in the various forms of truncus arteriosus and the commonly present ventricular septal defect (VSD).

Pluripotent neural crest cells play an important role in the development of the conotruncus and aortic arch. Deletion of *Cdc42* (cell division cycle 42), a GTP-binding protein that regulates cytoskeleton remodeling and is essential for neural crest cell migration, results in persistent truncus arteriosus and interrupted aortic arches in murine models.⁶ Selective ablation of neural crest cells in chick embryos before migration results in a number of congenital heart defects.⁷ These anomalies include truncus arteriosus and interrupted aortic arch, explaining their coexistence in approximately 10% to 20% of patients with truncus arteriosus.^{8,9}

Animal models provide further insight into the genetic basis for truncus arteriosus. The mouse mutant *Spitch*, which has a mutation in the homeobox gene *Pax3*, has a phenotype with truncus arteriosus and aortic arch abnormalities.¹⁰ In humans, monoallelic microdeletion of chromosome 22q11 is associated with multiple defects of neural crest origin, including typical facies, cleft palate, thyroid and parathyroid gland aplasia, and conotruncal

and aortic arch abnormalities. The resulting phenotypic syndromes include DiGeorge, velocardiofacial, and Shprintzen syndromes, which are associated with truncus arteriosus. One candidate gene identified in the area of the microdeletion is *HIRA*. *HIRA* interacts with *Pax3*, and thus may be integral to *Pax3* regulation of neural crest cells.¹¹ Environmental risk factors for the development of truncus arteriosus include maternal diabetes and exposure to retinoic acid.

Anatomy

In truncus arteriosus, there is generally situs solitus and D-looping of the ventricles. A single great vessel arises from the base of the heart, giving origin to the pulmonary, systemic, and coronary arteries. Classifications of truncus arteriosus were proposed by Collett and Edwards¹² in 1949 and by Van Praagh and Van Praagh¹³ in 1965 (Fig. 121-1). The system described by Collett and Edwards (Table 121-1) is based on the site of origin of the pulmonary arteries, whereas the Van Praagh classification (Table 121-2) is based on the degree of septation of the trunk and the presence or absence of a VSD. The Van Praagh scheme also requires that at least one of the pulmonary arteries arise from the common trunk. This stipulation appropriately relegates Collett-Edwards type IV, or *pseudotruncus*, to the spectrum of pulmonary atresia with aortopulmonary collaterals. The Van Praagh classification also provides for the inclusion of the relatively common association of hypoplastic or interrupted aortic arch. The term *hemitruncus* is frequently encountered in the literature to describe the anomalous origin of the right pulmonary artery from the ascending aorta with a normal origin of the left pulmonary artery from the main

pulmonary artery, usually in the absence of a VSD. This lesion is distinct from Van Praagh type B3 and should not be considered a form of truncus arteriosus.

A VSD is nearly always present. It results from the deficiency of the infundibular septum and is generally

TABLE 121-1 Collett and Edwards Classification

Type	Description
I	Branch pulmonary arteries arise from a segment of the main pulmonary artery off the common trunk.
II	Branch pulmonary arteries arise in close proximity from the posterior aspect of the common trunk.
III	Branch pulmonary arteries arise from separate, widely spaced origins.
IV	Absent “true” branch pulmonary arteries with aortopulmonary collaterals

TABLE 121-2 Van Praagh and Van Praagh Classification

Classification	Description
Type A	Ventricular septal defect present
Type B	Ventricular septal defect absent
1	Partial development of the aorticopulmonary septum
2	Absence of the aorticopulmonary septum
3	Absence of one of the branch pulmonary arteries
4	Coarctation, hypoplasia, or interruption of the aortic arch with a patent ductus arteriosus

FIGURE 121-1 ■ Comparison of the Collett and Edwards and the Van Praagh and Van Praagh classifications of truncus arteriosus.

FIGURE 121-2 ■ Right ventricular view of the pathologic anatomy of truncus arteriosus. The truncal origins of the aorta and left (L) and right (R) pulmonary arteries are apparent. The ventricular septal defect (D) is cradled between the inferior (IL) and superior (SL) limbs of the septal band (SB). Insertion of the IL into the parietal band (PB) provides muscular discontinuity between the tricuspid and truncal valves. *LBr*, Left bronchus; *LPA*, left pulmonary artery; *Tr*, trachea. (Reprinted with permission from Mair DD, Edwards WD, Julsrud PR, et al: Truncus arteriosus. In Allen HD, Gutgesell HP, Clark EB, Driscoll DJ, editors: *Moss and Adams' heart disease in infants, children and adolescents*, Philadelphia, 2001, Lippincott Williams & Wilkins, p 505.)

nonrestrictive. The VSD is cradled by the two limbs of the septal band and bounded superiorly by the truncal valve (Fig. 121-2). The posterior (inferior) limb of the septal band usually inserts into the parietal band, resulting in discontinuity of the tricuspid and truncal valves, maintaining a muscular rim between the conduction system and the VSD. When there is failure of insertion, the VSD extends into the membranous septum, with the conduction system running along the posterior-inferior rim of the defect.

The truncal valve can be tricuspid (69%), quadricuspid (22%), bicuspid (9%), or, rarely, unicuspid or pentacuspid.¹⁴ The valve is usually in continuity with the mitral valve and infrequently with the tricuspid valve. The truncus equally overrides both ventricles in 68% to 83% of cases, is deviated over the right ventricle in 11% to 29%, and is deviated to the left in 4% to 6%.^{7,15} The valve may be stenotic or regurgitant, which can complicate management of the patient with truncus arteriosus. A moderate or greater degree of truncal insufficiency is present in 20% to 26% of patients.^{16,17} Mild stenosis is generally detected on preoperative evaluation because of the increased flow across the truncal valve. Significant stenosis is present in only 4% to 7% of patients.^{16,17}

Gradients of greater than 30 mm Hg are concerning for residual stenosis after complete repair.¹⁸

The branch pulmonary arteries generally originate from the left posterolateral aspect of the truncus, just distal to the truncal valve. They are usually of good size without ostial or branch stenosis. Collett and Edwards type I is most frequently encountered, occurring in 48% to 68% of cases, followed by type II (29% to 48%) and type III (6% to 10%).^{7,15} In practice, most cases seem to fall into a category of "type 1½," with the branch pulmonary arteries arising not from a main pulmonary artery but in proximity from the posterior aspect of the truncus. Origin of one pulmonary artery from a systemic artery other than the truncus (Van Praagh type A3/B3) is relatively rare, with an incidence of 2% to 5%.^{16,19}

Associated Anomalies

An interrupted aortic arch, most commonly type B, is present in association with truncus arteriosus (Van Praagh type A4/B4) in approximately 10% to 20% of patients.^{8,9} The arch is rightward, generally with mirror image branching, in 21% to 36% of patients.^{8,20} Aberrant origins of the brachiocephalic vessels are reported, most commonly an aberrant right subclavian artery in 4% to 10%.^{15,20}

Coronary variations are common in truncus arteriosus and are of potential importance in the surgical repair of the lesion. The left anterior descending artery is often small, with prominent conal branches from the right coronary artery supplying the right ventricular infundibulum.²¹ The left anterior descending artery can originate from the right coronary artery, which has clear surgical ramifications for the right ventricular infundibulotomy. There is left coronary dominance in 27%, which is approximately threefold the incidence found in the general population.²² Coronary ostial abnormalities are of particular surgical significance and occur in 37% to 49% of cases.²² The usual arrangement, regardless of the number of cusps, is for the left coronary artery to arise from the left posterolateral cusp and for the right coronary artery to originate from the right anterolateral cusp. Coronaries can arise from a single orifice or from two ostia in a single cusp.⁸ There may be ostial stenosis, often described as a slitlike orifice, or obstruction from abnormal valve tissue. The left coronary artery is frequently noted to have a high origin, not uncommonly near the takeoff of the pulmonary arteries. Rarely, the left coronary artery can originate from the main pulmonary trunk or a branch pulmonary artery.¹⁵

Other cardiac anomalies are common, and a patent foramen ovale (PFO) is usually present. A true atrial septal defect is found in 9% to 20%, a persistent left superior vena cava in 4% to 9%, and mild tricuspid valve stenosis in 6%.^{15,20} Mitral valve abnormalities are reported in 5% to 10% of patients. Tricuspid atresia, complete atrioventricular septal defect, anomalies of pulmonary venous return, mitral atresia, hypoplastic left ventricle, ventricular inversion, and heterotaxy syndrome have all been reported in association with truncus arteriosus.

Extracardiac anomalies are reported in approximately 28% of patients with truncus arteriosus.¹⁷ Described

abnormalities include skeletal, genitourinary, and gastrointestinal deformities. As mentioned earlier, monoallelic microdeletion of chromosome 22q11 is common, and DiGeorge syndrome is diagnosed in at least 11%.¹⁷ These patients are at increased risk for more complicated operative courses, longer hospital stays, and greater resource utilization.²³

Pathophysiology

The pathophysiology of truncus arteriosus is one of a total admixture lesion, with mixing occurring at the level of the VSD and proximal truncus. Although there is cyanosis, systemic oxygen saturations are frequently 85% to 90% in the newborn period because of elevated pulmonary blood flow. In the absence of pulmonary artery stenosis or systemic outflow obstruction, the amount of pulmonary blood flow is mainly affected by the pulmonary vascular resistance (PVR). In the first few days of life, PVR remains relatively high, limiting pulmonary blood flow. As PVR decreases, the amount of pulmonary blood flow increases, leading to pulmonary overcirculation and signs and symptoms of congestive heart failure. The unrestricted left-to-right shunt results in both pressure and volume overload to the pulmonary circuit. In addition, truncus arteriosus is distinguished from other left-to-right shunt lesions by both systolic and diastolic shunting. These factors lead to the early development of irreversible pulmonary vascular occlusive disease in patients with truncus arteriosus.

Truncal valve regurgitation and, less frequently, stenosis can exacerbate the hemodynamic stresses placed on the heart in truncus arteriosus. Regurgitation adds an additional volume overload to the ventricles, worsening the signs and symptoms of congestive heart failure. The diastolic runoff, which occurs not only because of the insufficient valve but also as a result of the low-resistance pulmonary vascular bed, can lead to poor systemic perfusion, most notably to the coronary arteries. Stenosis increases the afterload on the ventricles and thereby increases myocardial oxygen demand. Significant truncal valve stenosis can limit systemic perfusion, again compounded by the runoff into the pulmonary circuit.

Diagnosis

Clinical Features

The diagnosis of truncus arteriosus is generally made in early infancy, often during the neonatal period. The lesion can also be recognized antenatally on fetal echocardiography. The degree of cyanosis or congestive heart failure depends on the PVR and the resultant volume of pulmonary blood flow. The clinical manifestations can be exacerbated by associated lesions, such as truncal valve insufficiency or interrupted aortic arch, or ameliorated by pulmonary artery stenosis.

Physical findings depend on the amount of pulmonary blood flow and the degree of truncal valve insufficiency. In general, the neonate with truncus arteriosus shows only mild cyanosis at the time of birth. As the PVR falls and pulmonary blood flow increases, signs of congestive

heart failure become manifest and cyanosis decreases. Truncal regurgitation accelerates the onset and increases the severity of congestive heart failure. The infant shows the typical findings of tachypnea, tachycardia, diaphoresis, and poor feeding. The precordium is hyperactive, and a thrill may be palpable over the left sternal border. There is a normal S1 and a single loud S2, which may be associated with an opening click. An S3 is not uncommon as the degree of failure progresses. A pansystolic murmur is common at the left sternal border. A low-pitched diastolic murmur at the apex, representing increased flow across the mitral valve, may be present. A high-pitched diastolic murmur along the left sternal border is indicative of truncal valve regurgitation. In the absence of the rarely encountered pulmonary artery stenosis, a continuous murmur is distinctly uncommon. The detection of a continuous murmur is consistent with other diagnoses, notably pulmonary atresia with a patent ductus or aortopulmonary collaterals. The peripheral pulse pressure is widened because of the diastolic runoff into the pulmonary bed and is further widened by truncal insufficiency.

Diagnostic Studies

The chest radiograph generally shows moderate cardiomegaly with increased pulmonary vascular markings. The arch is rightward in approximately one third of patients, and the thymus gland may be absent in those with 22q11 microdeletion. The combination of a right arch and increased pulmonary vascular markings is strongly suggestive of truncus arteriosus. The two-dimensional and Doppler echocardiography examinations are the diagnostic modalities of choice. The echocardiogram can define the anatomy of truncus arteriosus at birth or in utero. Prenatal echocardiography is increasingly identifying congenital heart anomalies; however, because of the challenges of imaging the branch pulmonary arteries, truncus arteriosus remains one of the more commonly misdiagnosed heart defects (78.6% accuracy).^{24,25} A parasternal long-axis view will demonstrate the large truncal valve overriding the VSD (Fig. 121-3A). The addition of Doppler interrogation will reveal truncal valve stenosis or regurgitation (see Fig. 121-3B). Suprasternal notch views can further define the anatomy of the pulmonary arteries and aortic arch (Fig. 121-4). Cardiac catheterization is generally reserved for the delineation of the anatomy in complex forms of truncus arteriosus, such as truncus arteriosus with a single pulmonary artery (Van Praagh type A3/B3). Cardiac catheterization is also indicated to assess PVR in the patient presenting late with truncus arteriosus. Magnetic resonance imaging (MRI) is a useful alternative or adjunct to cardiac catheterization for defining the anatomy of complex truncus arteriosus. MRI increasingly plays a role in the postoperative assessment of these patients in evaluating ventricular function as well as conduit and branch pulmonary artery anatomy.²⁶

Natural History

The typical natural history of truncus arteriosus is characterized by early demise because of congestive heart

FIGURE 121-3 ■ Parasternal long-axis view of a patient with truncus arteriosus. **A**, The large truncus (Tr) overriding the ventricular septal defect (VSD) is demonstrated. **B**, The addition of Doppler reveals a jet of truncal regurgitation (TrR). LA, Left atrium; LV, left ventricle; RV, right ventricle; TrV, truncal valve.

FIGURE 121-4 ■ Suprasternal notch view demonstrating close but separate origins of the right (R) and left (L) pulmonary arteries from the truncus (Tr) with continuation as the aorta (Ao).

failure. Death rates are approximately 40% at 1 month, 70% at 3 months, and 90% at 1 year.²⁷ Patients who survive infancy generally succumb by childhood or early adolescence because of congestive heart failure or, more commonly, pulmonary vascular obstructive disease. Rarely, patients survive infancy without developing pulmonary vascular obstructive disease, although those who do so are estimated to be less than 5% of all patients.²⁷

Treatment

Because of the inherent high early mortality, truncus arteriosus warrants early intervention. Initially, the surgical treatment of truncus arteriosus was limited to the banding of one or both of the branch pulmonary arteries. The first successful intracardiac repair was accomplished by Sloan's group at the University of Michigan in 1962 using an unvalved polytetrafluoroethylene (PTFE) conduit for the pulmonary reconstruction.²⁸ In 1967, McGoon and colleagues²⁹ performed the first valved

conduit repair, using an aortic allograft. During this period, complete repair was often undertaken as a staged procedure after initial pulmonary artery banding. However, complications of pulmonary artery banding, including pulmonary artery distortion, band migration, and failure to prevent the development of pulmonary vascular obstructive disease, resulted in a continued high mortality with this strategy. Ebert and coworkers³⁰ published the first series of patients undergoing repair of truncus arteriosus in infancy in 1984. With continued improvements in neonatal operative techniques, as well as perioperative care, management has evolved to earlier complete repair. After the early reports of neonatal repair from the University of Michigan¹⁸ and the Children's Hospital of Boston,³¹ neonatal repair has become the treatment of choice for truncus arteriosus.

Surgical Technique

The repair is performed using a standard median sternotomy. Although deep hypothermia with circulatory arrest or low-flow bypass has been advocated by some authors, the repair of simple forms of truncus arteriosus is performed easily on full-flow bypass with moderate hypothermia. More complex forms, such as Van Praagh type A3/B3 (one pulmonary artery absent) or A4/B4 (with interrupted aortic arch), may require periods of deep hypothermic circulatory arrest. The arterial cannula is placed distally in the ascending aorta at the base of the innominate artery. Bicaval cannulation is used for venous return, with an additional left ventricular vent placed through the right upper pulmonary vein. The pulmonary arteries are mobilized and snared to direct cardiopulmonary bypass flow to the systemic circulation.

The heart is arrested with antegrade cardioplegia, with the aortic crossclamp placed as distally as possible. Significant truncal valve regurgitation may necessitate the use of retrograde cardioplegia. Once the cardioplegia is delivered, the pulmonary arteries are removed. If the coronary arteries can be positively identified and the exposure is adequate, the pulmonary arteries can be removed directly from the posterior aspect of the truncus,

FIGURE 121-5 ■ Repair of truncus arteriosus. Removal of the pulmonary arteries from the truncus is facilitated by an anterior longitudinal aortotomy (A) or by transecting the aorta (B).

particularly for Collett and Edwards type I truncus arteriosus. The ostia of the coronary arteries can originate high in the sinuses or have an intramural course.³² Direct assessment of the coronary anatomy in the aortic root is crucial if there is any uncertainty. Often, it is helpful to open the aorta anteriorly to aid in the removal of the pulmonary arteries and to identify the origins of the coronary arteries (Fig. 121-5A). Transection of the aorta just distal to the origins of the branch pulmonary arteries is another useful technique to facilitate pulmonary artery and coronary exposure (see Fig. 121-5B). The pulmonary arteries are removed, together with a small rim of adjacent truncal wall. Care is taken to avoid injuring the left coronary artery or truncal valve, which are often in close proximity to the pulmonary arteries. The truncal defect is then repaired primarily or with a patch of PTFE. At this point, additional doses of cardioplegia can be given at intervals, depending on surgeon's preference.

The heart is inspected for the presence of any large conal branches, the location of the left anterior descending artery, and the possibility of aberrant coronary arteries. A right infundibulotomy is then made in an avascular area of the right ventricular outflow tract. The infundibulotomy is carried cranially toward the truncal valve and is limited to the size necessary to allow unobstructed output from the right ventricle through the anticipated conduit (Fig. 121-6A). Through the infundibulotomy, the VSD is closed with a patch of PTFE. We use a running suture technique, although an interrupted

FIGURE 121-6 ■ Repair of truncus arteriosus. A, The ventricular septal defect (VSD) is exposed through a right infundibulotomy. B, The VSD patch is transitioned to the epicardium at the superior-most portion of the infundibulotomy. The posterior aspect of the pulmonary allograft is sewn directly to the superior portion of the infundibulotomy.

technique can be used as well. When there is membranous or inlet extension of the VSD, care is taken not to injure the conduction tissue in the posteroinferior aspect of the VSD. It is helpful to transition from the endocardium of the right ventricular outflow tract to the epicardium in the anterosuperior-most portion of the infundibulotomy, to avoid injuring the truncal valve and to ensure a widely patent left ventricular outflow tract (see Fig. 121-6B). If present, the atrial septal defect is then closed. A small PFO can be left as a “popoff valve” to aid in postoperative management.

Once the VSD is closed, the remainder of the procedure can be performed with the crossclamp removed and the heart beating. We prefer to use cryopreserved pulmonary or aortic allografts for reconstruction of the pulmonary outflow tract, although either bovine jugular vein grafts or heterograft valved conduit are viable alternatives. The distal anastomosis of the allograft is performed to the confluence of the native branch pulmonary arteries. The posterior aspect of the allograft is then approximated to the superior portion of the right infundibulotomy. Anteriorly, the conduit is augmented with a patch of PTFE or additional allograft material (Fig. 121-7). A

FIGURE 121-7 ■ Repair of truncus arteriosus. Right ventricle-to-pulmonary artery continuity is then completed with a hood of polytetrafluoroethylene.

benefit of the bovine jugular vein grafts is the proximal extension of tissue, which can be used to patch the right infundibulotomy without additional patch material.

Other Surgical Considerations

Interrupted Aortic Arch

The surgical repair of truncus arteriosus with interrupted aortic arch (Fig. 121-8) requires several modifications to the basic operative procedure. The aortic cannulation is performed proximally at the base of the innominate artery to perfuse all of the brachiocephalic vessels, and distally in the ductus arteriosus to perfuse the distal aorta. Bicaval cannulation is used for venous return, with a left ventricular vent placed through the right upper pulmonary vein. The patient is placed on cardiopulmonary bypass and cooled to 18° C for a minimum of 20 minutes. The pulmonary arteries are snared to prevent pulmonary overcirculation. During cooling, the ascending aorta, arch, proximal descending aorta, brachiocephalic vessels, and pulmonary arteries are mobilized. The arch repair can be performed under deep hypothermic circulatory arrest. Alternatively, regional cerebral perfusion, as described by Pigula and coworkers³³ and others, can be performed by anastomosing a PTFE tube graft to the innominate artery or by directly cannulating the aorta at the base of the innominate artery and advancing the cannula into the innominate. After adequate cooling, the head vessels are snared, bypass is discontinued, and regional cerebral perfusion is initiated, if desired. The

FIGURE 121-8 ■ Truncus arteriosus (Collett and Edwards type II) with a type B interrupted aortic arch.

FIGURE 121-9 ■ Repair of truncus arteriosus with interrupted aortic arch. The ductus arteriosus has been ligated and divided, and the pulmonary arteries have been removed from the truncus. The areas for spatulation on the ascending aorta and proximal descending aorta are indicated (dashed lines).

ductus arteriosus is ligated just distal to the origin of the pulmonary arteries and divided. All residual ductal tissue is resected from the proximal descending aorta. The ascending aorta and proximal descending aorta are spatulated (Fig. 121-9). The back walls of the distal ascending aorta and proximal descending aorta are approximated, and the repair is augmented with a patch of cryopreserved pulmonary allograft (Fig. 121-10). Once the arch reconstruction is completed, the aorta can be recannulated and de-aired, an aortic crossclamp can be placed, and cardiopulmonary bypass can be resumed. Additional doses of cardioplegia can be administered and rewarming can begin. The remainder of the repair, including VSD closure and pulmonary outflow tract reconstruction, is similar to the simple truncus arteriosus surgical procedure.

FIGURE 121-10 ■ Repair of truncus arteriosus with interrupted aortic arch. The distal ascending and proximal descending aorta are reapproximated and augmented with cryopreserved pulmonary allograft.

Truncal Valve Regurgitation or Stenosis

Significant truncal valve regurgitation, or, less frequently, stenosis, can complicate the operative management of truncus arteriosus in approximately a quarter of cases. A conservative approach is warranted, as frequently both regurgitation and stenosis improve after corrective surgery and relief of the volume overload. Gradients of less than 30 mm Hg generally do not require intervention.¹⁸ In addition, even moderate degrees of truncal regurgitation are well tolerated, and delay of valve repair or replacement can often be accomplished. A recent analysis of the Society of Thoracic Surgeons Congenital Heart Surgery database from 2000-2009 demonstrated that concomitant truncal valve surgery at the time of truncus arteriosus is associated with a significantly higher operative mortality compared with repair of the truncus arteriosus in isolation (30% vs. 10%; $P = 0.0002$). This mortality risk increases to 60% when the truncal valve surgery is combined with repair of an interrupted aortic arch—the caveat being that patients who did not have an initial truncal valve surgery, but subsequently required surgical intervention during their index hospital admission, had a 100% mortality.³⁴ Hence, appropriate patient selection is essential in terms of timing of truncal valve intervention. Many patients with severe truncal regurgitation do not survive to operation. For the patients who do survive, the presence of moderate to severe truncal regurgitation after the initial operation is a risk factor for late truncal valve reintervention but not early mortality.³⁵ At the time of truncal valve intervention, truncal valve repair is preferred if the valve is amenable with other options, including root replacement with cryopreserved aortic allograft or mechanical valve replacement. Truncal valve replacement can be facilitated by enlargement of the valve annulus by the VSD patch. For truncal valve repair, several techniques have been described in

small series of patients with reasonable survivals. These techniques include annuloplasty, resection of cusps, closure of commissures, resuspension of cusps, and cusp repair.^{36,37} Backer and Mavroudis^{38,39} have reported that truncal valve remodeling by leaflet excision or reduction annuloplasty is the most effective and durable method of truncal valve repair. In long-term follow-up, this group demonstrated that durable results can be achieved with valve morphology as the key determinant of success, with 75% of patients having a quadricuspid valve requiring leaflet excision and tricuspidization of the valve, with only two patients proceeding to valve replacement 9 and 10 years after repair.⁴⁰ Risk factors for reoperation following truncal valve repair include neonatal repair (hazard ratio 4.1; $P = 0.03$) and performance of leaflet thinning (hazard ratio 22.5; $P = 0.002$).⁴¹ Older children and adults have a greater number of options for valve replacement, including aortic allograft, stented or stentless tissue valves, and mechanical valves. Repair is also an option in this population if the anatomy is amenable to a durable repair.

Pulmonary Outflow Tract Reconstruction

Although the majority of surgeons use valved heterograft or allograft conduits, several other techniques have been described. These other techniques include the use of unvalved conduits, fresh autologous pericardial valved conduits, monocusps, and various methods for achieving native tissue apposition between the right ventricle and the pulmonary artery.

Unvalved tube grafts have been used in the past with good results, but they have been largely abandoned with the development of appropriately sized valved conduits.⁴² Advantages include availability and lower risk of stenosis related to valve dysfunction or calcification. The clear disadvantage is the lack of a valve in the immediate postoperative period, with free regurgitation into a right ventricle compromised by a ventriculotomy and periods of ischemia and cardiopulmonary bypass. In addition, a valve may be advantageous in neonates with labile PVR or in older patients with pulmonary vascular obstructive disease. One study analyzing neonatal repair with unvalved conduits found that patients with truncus arteriosus had the highest rate of reintervention for conduit failure compared with other diagnostic groups.^{43,44}

Options for valved conduits include composite heterografts, allografts, and bovine jugular vein grafts. Porcine heterografts in Dacron tube grafts are available in sizes as small as 12 mm. Advantages include ready availability. Disadvantages are primarily related to the stiff Dacron tube graft, which is less hemostatic and less forgiving, with a greater risk of distortion of the branch pulmonary arteries. Dacron also tends to form a neointimal peel, potentially leading to stenosis. In addition, the rigid metal ring of the heterograft valve can be compressed beneath the sternum, obstructing the left anterior descending artery. Bovine jugular vein grafts have increased in popularity. They are readily available in small sizes, down to 12 mm. These grafts have excellent handling characteristics, are hemostatic, and minimize branch pulmonary artery distortion. They are available with or without supporting rings to minimize distortion

from sternal compression. The bovine jugular vein grafts have similar durability to traditional allografts, however enthusiasm has been tempered by increased risk of distal stenosis especially in patients younger than 2 years.^{45,46,47} Another larger series has shown the Contegra conduit and size less than 20 mm to be independent risk factors for need for graft replacement when compared with allografts.⁴⁸

Cryopreserved pulmonary allografts have the advantages of excellent tissue handling characteristics and ease of implantation. Aortic allografts can also be used, although they appear to be less durable than their pulmonary counterparts.^{17,49} The disadvantage of these conduits is primarily related to the limited availability in the very small sizes, although allografts in the range of 12 to 16 mm can generally be placed in neonates without difficulty. A larger pulmonary allograft can be downsized by removal of one of the cusps, creating a bicuspid valve. Our group and others⁵⁰⁻⁵² have successfully used this technique when appropriately sized allografts are unavailable.

Whether heterografts or allografts have superior longevity remains controversial. Several published studies, including our own experience, have shown that pulmonary allografts are the optimal conduit in neonates and infants.^{17,53} Our results for the placement of a right ventricle-to-pulmonary artery conduit in a series of 155 infants demonstrated a significantly greater 5-year freedom from reoperation for cryopreserved pulmonary allograft (50%) compared with aortic allograft (24%; $P = 0.02$) and heterograft (26%; $P = 0.05$).³⁹ It has been shown that optimizing allograft size (z-score within +1 to +3) is important to conduit longevity, with no additional benefit from oversizing conduits.^{45,54} Others have found no significant difference in longevity between heterografts and allografts for the repair of truncus arteriosus.⁵⁵

In an effort to decrease the need for reoperation, several groups have suggested methods for achieving native tissue apposition in the right ventricular outflow tract to allow for growth. In 1990, Barbero-Marcial and associates⁵⁶ introduced a technique for anastomosing the pulmonary bifurcation directly to the superior margin of the infundibulotomy. The anterior aspect of the anastomosis is then augmented with a patch, which includes a monocusp. Late follow-up of 45 patients by Barbero-Marcial and Tanamati⁵⁷ demonstrated that this technique resulted in a reintervention rate of 12% over a mean follow-up of 47 months, with an 11.4-year actuarial survival rate of 67.5%. In addition, 44.4% had moderate to severe pulmonary regurgitation and 23.3% had pulmonary stenosis. Lacour-Gayet and colleagues¹⁶ reported their experience with 56 consecutive patients undergoing repair for truncus arteriosus using a number of different techniques for pulmonary outflow tract reconstruction. They found equivalent rates of reintervention for heterograft and direct anastomosis of approximately 80%. Danton and associates⁵⁸ published a series of 61 patients with truncus arteriosus, 38 repaired with a conduit and 23 with direct anastomosis. Although mortality was not influenced, 10-year actuarial freedom from reoperation was 89% in the direct anastomosis group, compared with 56% in the conduit group ($P = 0.023$).

Right ventricular outflow tract reconstruction using fresh autologous pericardial valved conduits has been described by Kreutzer and associates.⁵⁹ Their series of 86 patients undergoing this technique included 23 cases of truncus arteriosus. Operative mortality for the patients with truncus arteriosus was 26%. Among the entire group, moderate to severe conduit regurgitation was present immediately after surgery in 12.7%. By 6 months after surgery, no valve tissue could be identified in any patient, either by echocardiography or by visual inspection in those patients requiring reoperation. For the entire cohort, the need for conduit-related reintervention was 83% at 5 years and 60% at 10 years for conduits less than 16 mm at the time of implantation. By contrast, in the report by Lacour-Gayet and coworkers,¹⁶ freedom from reoperation or angioplasty at 7 years was 100% for patients receiving a pericardial conduit in the repair of truncus arteriosus. However, the authors also found the use of direct anastomosis or pericardial conduit to be a significant risk factor for operative mortality (43%), when compared with a heterograft or allograft (7.1%; $P = 0.015$).

Postoperative Management

Most patients require low doses of inotropic support with standard postoperative care techniques. The placement of a left atrial transthoracic monitoring line is helpful, as the central venous pressure may not accurately reflect left-sided filling pressures because of right ventricular dysfunction. Early operation has virtually eliminated the postoperative pulmonary hypertensive crises seen in earlier studies. For older patients in whom pulmonary vascular hypertensive crisis or pulmonary vascular obstructive disease can be anticipated, the placement of a transthoracic pulmonary artery line can aid in postoperative management. Avoiding acidosis, hypercarbia, and hypoxia can minimize PVR. Sedation and paralysis are also used to minimize fluctuations in PVR. The use of nitric oxide and sildenafil can induce pulmonary vascular smooth muscle relaxation and can be particularly useful in older patients with reversible pulmonary vascular obstructive disease.

Results

Since the first large series of truncus arteriosus repair in infants by Ebert and colleagues³⁰ in 1984, the management has evolved to earlier neonatal repair, with a continual improvement in survival. Hospital mortality for the neonatal repair of truncus arteriosus from the Society of Thoracic Surgeons Congenital database from 2005 to 2009 was 10.9% (range, 0%-100%).⁶⁰ The majority of deaths occur in patients with complex truncus arteriosus or truncus arteriosus associated severe truncal valve regurgitation.^{16-19,32,61} More complex forms of truncus arteriosus are also associated with increased hospital morbidity and prolonged length of stay.⁶² Risk factors for poor outcome identified in various studies include significant truncal regurgitation, need for truncal valve replacement, birth weight less than 2.5 kg, presence of interrupted aortic arch or coronary artery anomalies,

pulmonary reconstruction with a technique other than valved heterograft or allograft, and age greater than 100 days.^{16-19,31,55,61} Some single-center studies have demonstrated that interrupted aortic arch is not a risk factor.^{18,19} However, a recent Congenital Heart Surgeons' Society study and a single-center study have again shown a high early mortality rate of 42% to 56% for truncus arteriosus associated with interrupted aortic arch.^{63,64}

Long-term survival for patients with truncus arteriosus is also encouraging with actuarial survivals of 90% at 5 years, 85% at 10 years, and 83% at 15 years, with the majority of survivors (97%) in New York Heart Association class I or II.^{20,55} Examination of the Kaplan-Meier survival curves reveals that the majority of mortality is associated with the initial operation. Late follow-up has demonstrated that although the greatest need for intervention or hospitalization is in the first year of life, patients with truncus arteriosus have significantly impaired exercise capacity and diminished physical health status and health-related quality of life compared to normative standards.⁶⁵ An issue for patients with a variety of conotruncal abnormalities is the finding of a dilated ascending aorta in adolescents and adults and the question of whether this requires intervention. The majority of patients have been found to have an aorta z-score of ≥ 2 ; however, the risk of dissection is believed to be rare and therefore conservative management with close observation is the recommended approach at this time.^{66,67}

AORTOPULMONARY WINDOW

Aortopulmonary window is an uncommon malformation characterized by an anomalous communication between the adjacent portions of the ascending aorta and the main pulmonary artery. Distinctively, the aortic and pulmonary semilunar valves are both present, and the ventricular septum is typically intact. This lesion represents between 0.2% and 0.3% of all congenital heart lesions.^{68,69} Aortopulmonary window was first described by Eliotson in a clinicopathologic discussion given at St. Thomas' Hospital in London in 1830.⁷⁰

Embryology

Descriptions of cardiac embryology can be confusing because of varying terminology used by different authors. For the purpose of this discussion, the embryonic cardiac outflow tract can be considered as the portion of the primitive heart tube that connects the ventricles with the aortic arch vessels. This outflow tract comprises the conus, the truncus, and the aortic sac. Histologically, the conotruncus has an external muscle layer and internal cardiac jelly (which is cellular), whereas the aortic sac has a wall consisting of endothelium surrounded by loose mesenchyme. Septation of the outflow tract seems to occur in a craniocaudal direction by two mechanisms.⁷¹ Initial septation occurs by an ingrowth of mesenchyme (principally neural crest tissue), which separates the aortic sac into the definitive aorta and the pulmonary artery. This aorticopulmonary septum then extends caudally to divide the distal truncus. Meanwhile, in the proximal

conotruncus, paired ridges (consisting of both neural crest and non-neural crest tissue) bulge into the lumen and meet. The caudal portion of the aorticopulmonary septum ultimately fuses with the cranial extent of the conotruncal ridges to complete septation. This entire process occurs in human embryos beginning when the crown-rump length is 6 mm, and it is completed by the 9-mm stage over a period of approximately 5 days.⁷²

The embryologic defect in aortopulmonary window is presumed to be related to nonfusion of the aorticopulmonary septum with the conotruncal septum, malalignment of the two septa, or complete absence of the aorticopulmonary septum.⁶⁹ The defects leading to truncus arteriosus and aortopulmonary window are thought to be distinct. Although a number of gene mutations that lead to a phenotype of truncus arteriosus have been identified, none of these has resulted in isolated aortopulmonary window. In addition, isolated aortopulmonary window is generally not seen in the constellation of conotruncal abnormalities that occur in conjunction with DiGeorge syndrome.

Anatomy

The defect in aortopulmonary window is usually oval and solitary, although its precise location can vary. Many classification schemes have been proposed to describe the variation in morphology of this anomaly. One widely used classification, proposed by Richardson and colleagues, describes three variants.⁷³ Type I defects represent the classic proximal window involving the posteromedial wall of the ascending aorta just above the left sinus of Valsalva and the adjacent wall of the main pulmonary artery. The inferior extent of the proximal defect may be close to the origin of the left coronary artery. Type II defects are more distal communications occurring near the origin of the right pulmonary artery. Distal windows can be associated with a variable degree of "unroofing" of the right pulmonary artery, which can lead to the apparent origin of this vessel from the posterolateral aspect of the ascending aorta. Finally, type III defects describe anomalous origin of the right pulmonary artery from the posterolateral wall of the ascending aorta (without an associated window). The type III defect has also been called *hemitruncus*, although the use of this term has been discouraged in favor of the more descriptive "anomalous origin of the right pulmonary artery from the aorta."

A more useful scheme was advanced by Mori and associates.⁷⁴ In the Mori classification, type I and II defects are analogous to their counterparts in the Richardson classification, with type I (proximal) defects occurring between the adjacent portions of the proximal ascending aorta and main pulmonary artery, and type II (distal) defects located more distally near the origin of the right pulmonary artery. Mori type III (total) defects are large defects representing a combination of types I and II.

Recently, Jacobs and members of the Congenital Heart Surgery Nomenclature and Database Project proposed general use of the Mori classification (proximal, distal, and total), with the addition of a fourth type termed intermediate and representing a window similar to the total defect but slightly smaller, with well-defined

FIGURE 121-11 ■ Anatomy and classification of aortopulmonary window as recommended by the Congenital Heart Surgery Nomenclature and Database Project. **A**, Type I (proximal) defects occur between adjacent portions of the proximal ascending aorta and the main pulmonary artery. **B**, Type II (distal) defects are located more distally, near the origin of the right pulmonary artery. **C**, Type III (total) defects are large defects with poorly defined margins representing a combination of types I and II. Intermediate defects (not illustrated) are similar to total defects but are slightly smaller and have well-defined superior and inferior rims.

superior and inferior rims.⁷⁵ The remainder of this chapter will adhere to this terminology. [Figure 121-11](#) illustrates the anatomic subtypes of aortopulmonary window.

Associated Anomalies

Associated anomalies can occur in 25% to 65% of cases of aortopulmonary window.^{69,76-79} These associated defects may be considered minor or major.⁸⁰ Common minor defects include right aortic arch, patent ductus arteriosus, atrial septal defect, and PFO. Major defects commonly seen with aortopulmonary window include interrupted aortic arch (usually type A), tetralogy of Fallot, VSD, anomalous coronary artery, coarctation of the aorta, and univentricular heart lesions. Berry and colleagues⁸¹ described a syndrome characterized by a distal aortopulmonary window, aortic origin of the right pulmonary artery, intact ventricular septum, patent ductus arteriosus, and interruption or coarctation of the aortic isthmus. Braunlin and coworkers⁸² emphasized the frequency of arch obstruction in patients with an aortopulmonary window, reporting interrupted aortic arch in

43% and coarctation in 14%. The presence of an aortopulmonary window must always be excluded in infants with an interrupted aortic arch and an intact ventricular septum. A high index of suspicion for an aortopulmonary window is also warranted in cases of unexplained pulmonary artery hypertension or cardiac dilation.⁸³

Pathophysiology

An aortopulmonary window invariably leads to excessive pulmonary blood flow secondary to a large-volume left-to-right shunt that occurs during systole and diastole. The degree of shunting is, of course, determined by the size of the window and the ratio of systemic to pulmonary vascular resistance. The window is usually nonrestrictive in nature, thereby leading to equalization of pressures in the aorta and pulmonary arteries. As PVR decreases after birth, shunt volume increases. The result is left ventricular volume overload, as well as a pressure load on the right ventricle. Excessive pulmonary blood flow can lead acutely to the development of interstitial pulmonary edema. Over time, pulmonary overcirculation can lead to the development of pulmonary vascular obstructive disease.

The presence of associated defects can affect the physiology of this condition. Most importantly, the presence of aortic arch obstruction exacerbates left-to-right shunting across the aortopulmonary window. In cases of severe coarctation or arch interruption, in which systemic perfusion is ductal dependent, closure of the ductus will precipitate severe systemic malperfusion and divert even more blood flow to the lungs.

Diagnosis

Clinical Features

As with truncus arteriosus, the diagnosis of aortopulmonary window is generally made during infancy. A loud continuous murmur with systolic accentuation is heard best at the left upper sternal border and may be confused with the murmur associated with a patent ductus arteriosus. The second heart sound may be accentuated and narrowly split. The diastolic blood pressure is usually reduced, with a concomitant widened pulse pressure and, on occasion, a water-hammer pulse. Patients typically present with symptoms of congestive heart failure (tachypnea, diaphoresis, failure to thrive, or recurrent respiratory infections).

The differential diagnosis of aortopulmonary window includes patent ductus arteriosus, truncus arteriosus, VSD with aortic insufficiency, and ruptured sinus of Valsalva aneurysm.

Diagnostic Studies

A chest radiograph demonstrates moderate cardiomegaly and increased pulmonary vascular markings. A right aortic arch may be present.

Echocardiography is generally diagnostic and has replaced angiography as the gold standard.⁸⁴⁻⁸⁸ The margins of the window can be imaged with two-dimensional echocardiography, and Doppler color-flow

FIGURE 121-12 ■ Echocardiographic views in a patient with a large (total-type) aortopulmonary window (as well as a type A interrupted aortic arch). **A**, Subcostal coronal view shows the large communication (arrow) between the ascending aorta (Ao) and the main pulmonary artery (PA). **B**, Parasternal short-axis view demonstrates that the distal extent of the aortopulmonary window involves the origin of the right pulmonary artery (RPA). The anterior border of the window is identified by the arrow.

mapping can confirm flow across the communication. The most useful echocardiographic views to delineate the margins of the window include the suprasternal long axis, the subcostal coronal plane through the pulmonary trunk, and the high parasternal short plane cephalad to the aortic valve (Fig. 121-12). Additional echocardiographic findings include left atrial and left ventricular enlargement, which are usually in proportion to the degree of volume overload. Continuous forward flow in the distal main or branch pulmonary arteries is evident. When a jet of tricuspid or pulmonary insufficiency is present, pulmonary hypertension can be confirmed. The diagnosis of aortopulmonary window can also be made during fetal echocardiography.⁸⁹ MRI is an emerging technique that is capable of clarifying anatomy with great detail.^{90,91}

Cardiac catheterization is rarely necessary unless clarification of associated defects is needed or if the coronary anatomy cannot be imaged well by echocardiography. In patients who present beyond infancy, catheterization allows the calculation of PVR to determine surgical candidacy.

Natural History

Patients with large aortopulmonary windows generally do not survive beyond childhood. Of untreated patients, 40% die within the first year of life.⁹² Untreated patients generally develop pulmonary vascular obstructive disease. Because of the poor prognosis associated with this condition, it is recommended that all patients with aortopulmonary window undergo repair.

Treatment

The initial repair of aortopulmonary window involved, of necessity, closed techniques. Robert Gross performed the first surgical closure of an aortopulmonary window in 1948.⁹³ The patient was a 4-year-old girl who was explored via a left thoracotomy for a presumptive patent ductus arteriosus. The correct diagnosis was made at

operation. Gross successfully ligated the window but acknowledged the potential risks and limitations of this technique. Scott and Sabiston⁹⁴ developed an animal model for aortopulmonary window and then devised techniques for closed division and suture closure using partial occluding clamps; they subsequently applied these techniques clinically in 1951. These closed techniques, however, were associated with several major limitations. First, dissection of the window was fairly risky because of potential bleeding complications. Second, division and primary closure of the window could lead to significant narrowing of both the aorta and the pulmonary artery and potential distortion of the semilunar valves. Third, the closed approach did not allow visualization of the coronary ostia, so coronary perfusion might be compromised after repair.

The introduction of cardiopulmonary bypass brought a greater margin of safety to the closed approach, but, more importantly, cardiopulmonary bypass permitted the development of open techniques that could be applied to the repair of all types of aortopulmonary window defects and their associated defects. Cooley and colleagues were the first to use cardiopulmonary bypass to facilitate division and oversewing of an aortopulmonary window in 1956.⁹⁵ Since that time, most published reports have emphasized the adjunctive use of cardiopulmonary bypass. In 1966, Putnam and Gross suggested a transpulmonary approach to repair, whereby the defect could be sutured closed from within the lumen of the main pulmonary artery using a longitudinal arteriotomy.⁹⁶ Although most early repairs were performed in older children, Cordell and associates reported the first closure of an aortopulmonary window in an infant (6 months of age) in 1967.⁹⁷ Wright and coworkers⁹⁸ described suture closure of the defect via a transaortic approach. This approach provided excellent exposure of the margins of the defect and the origins of the left coronary artery and right pulmonary artery. In 1969, Deverall and colleagues⁹⁹ reported their experience using a transaortic approach with closure of the defect using a Dacron patch. The

advantages of patching the defect with a transaortic approach were emphasized in a report from Clarke and Richardson.¹⁰⁰ This became the early standard approach for most cases of aortopulmonary window. Operative mortality was significantly reduced with this change in operative strategy.⁷⁶ Studies in the early twenty-first century have demonstrated that early repair, preferably in infancy, along with concomitant repair of associated anomalies is imperative for optimal outcomes.¹⁰¹⁻¹⁰³

The preoperative care of patients with aortopulmonary window primarily involves the management of associated congestive heart failure using standard techniques. Patients with significant aortic arch obstruction require infusion of prostaglandin E₁.

All symptomatic patients should undergo prompt repair, once the diagnosis is confirmed. Asymptomatic patients should undergo repair by 3 to 4 months of age to avoid the development of pulmonary vascular obstructive disease, which can occur in some patients at as early as 6 months of age. Older patients should undergo preoperative catheterization to assess PVR and its response to oxygen and nitric oxide. A ratio of pulmonary vascular resistance (Rp) to systemic vascular resistance (Rs) of greater than 0.4 has been shown to be a risk factor for perioperative death.¹⁰⁴ A PVR greater than 8 to 10 and an Rp/Rs greater than 0.7 probably represent absolute contraindications for repair.

Surgical Technique

The repair is performed using standard median sternotomy. Bicaval venous and distal aortic cannulation is recommended. Snare is placed around both branch pulmonary arteries. Cardiopulmonary bypass with moderate hypothermia is initiated, and pulmonary arterial snares are tightened. After aortic cross-clamping, standard cardioplegia is delivered via the aortic root. Subsequent doses of cardioplegia (if necessary) are readily given by retrograde or direct antegrade approach.

Many centers continue to use the transaortic approach for the repair of aortopulmonary window. A longitudinal aortotomy is made in the ascending aorta. For simple proximal (type I) defects, closure is readily accomplished using a PTFE patch (Fig. 121-13). Care must be taken to identify and protect the left coronary orifice. For distal (type II) defects, a more extensive patch must be fashioned (Fig. 121-14). When there is considerable unroofing of the right pulmonary artery, the creation of an intra-aortic baffle can result in aortic obstruction; this can be alleviated by simply closing the aortotomy with an elliptical patch (Fig. 121-15). Total (type III) and intermediate-type defects are repaired using analogous techniques (Fig. 121-16).

Johansson and colleagues⁸⁵ described a transwindow approach (also called a *sandwich-type repair*), which has gained wide acceptance as the optimal approach for the repair of aortopulmonary window. In this technique (Fig. 121-17), an incision is made in the anterior wall of the communication between the aorta and the pulmonary trunk. A patch is then sutured to the posterior wall of the defect. The suture line is subsequently carried anteriorly to incorporate the patch in the closure of the arteriotomy.

FIGURE 121-13 ■ Transaortic patch repair of a proximal aortopulmonary window. **A**, A vertical aortotomy in the proximal ascending aorta provides excellent exposure. **B**, Patch closure of the defect. Care must be taken to identify and protect the origin of the left coronary artery.

FIGURE 121-14 ■ Repair of a distal aortopulmonary window. **A**, A more distal aortotomy exposes the defect that is related to the origin of the right pulmonary artery. **B**, Use of a generous patch avoids stenosis of the origin of the right pulmonary artery.

This approach has the advantage of being slightly quicker to perform, as there is no need to close a separate aortotomy.

Several authors have used a pulmonary flap technique to avoid the use of prosthetic patch material to

FIGURE 121-15 ■ Repair of a distal aortopulmonary window with extensive unroofing of the right pulmonary artery. **A**, Extensive unroofing leads to the appearance of anomalous origin of the right pulmonary artery from the ascending aorta. **B**, An extensive intra-aortic baffle created to join the window to the origin of the right pulmonary artery. **C**, Obstruction of the lumen of the ascending aorta can be obviated by closing the aortotomy with an elliptical patch.

reconstruct the ascending aorta.¹⁰⁵⁻¹⁰⁸ In this approach, an anterior flap of pulmonary artery is incised in continuity with the aorta along the anterior border of the window. The anterior flap is then sewn to the posterior margin of the aortopulmonary window, thereby closing the defect in the aorta. The resultant defect in the pulmonary artery is then closed with a patch (autologous or heterologous).

Kitagawa and associates¹⁰⁹ reported an alternative technique to repair a distal aortopulmonary window with extensive unroofing of the right pulmonary artery. In this approach, the ascending aorta is transected at the distal extent of the window, and the right pulmonary artery is excised along with a strip of posterior aorta in continuity with the window and pulmonary trunk. The defect in the pulmonary artery is then repaired either primarily or using a patch, and the aorta is reconnected primarily. This technique has the advantage of avoiding any potential problems resulting from an intra-aortic baffle.

Other Surgical Considerations

Associated defects are generally repaired concurrently. Special consideration should be given to the repair of

FIGURE 121-16 ■ Repair of a total-type (or intermediate-type) aortopulmonary window. **A**, Exposure is achieved with an extensive aortotomy. **B**, A large patch is used to close the defect.

FIGURE 121-17 ■ Transwindow (sandwich) repair of aortopulmonary window. **A**, An incision is made in the anterior wall of the window. **B**, A patch is then sewn to the posterior border of the defect. **C**, Finally, the anterior portion of the defect is closed by incorporating the patch in the closure of the aortotomy.

defects associated with arch interruption, as this is associated with increased mortality and the need for late reoperation.^{110,111} Because of the presence of the window, single arterial cannulation of the ascending aorta is sufficient. Cardiopulmonary bypass with deep hypothermia is used (with occlusion of the branch pulmonary arteries). The repair is typically performed under circulatory arrest or with adjunctive regional cerebral perfusion. The ductus is ligated proximally, and ductal tissue is resected distally. Two operative strategies can then be considered. Using a conventional approach, the arch interruption can be repaired first (using standard techniques), followed by repair of the window (transaortic patch or sandwich-type repair). Alternatively, the ascending aorta can be separated from the pulmonary artery at the level of the window, leaving defects in both vessels. The aortic arch is then reconstructed with patching of the defect in the ascending aorta, if necessary. Finally, the defect in the pulmonary artery is repaired with a patch.

Interventional Techniques

On rare occasions, a native aortopulmonary window or residual aortopulmonary defect after surgical closure may be small enough to allow an interventional approach. Several groups have reported success using percutaneously placed devices to close such defects.¹¹²⁻¹¹⁶ With improved devices and experience, even large, nonrestrictive aortopulmonary windows in infants have been closed with a transcatheter approach when the anatomy is appropriate.^{117,118} Following device closure, patients need to be followed for the development of aortic regurgitation at the time of the procedure as well as long-term.¹¹⁹ For now, however, surgical closure remains the standard of care.

Postoperative Management

Currently, because the diagnosis and treatment of aortopulmonary window are accomplished in early infancy, pulmonary hypertensive crises are rare. However, in patients presenting later in life, management of pulmonary hypertension is the most critical aspect of postoperative care of patients undergoing repair of aortopulmonary window. A pulmonary arterial catheter can be placed with a pursestring in the right ventricular infundibulum in selected patients. Conventional methods for the control and prevention of pulmonary hypertension include the use of inhaled nitric oxide, administration of other pulmonary vasodilators, liberal use of fentanyl and muscle relaxants, and mild hyperventilation.

Results

Early mortality following the repair of simple aortopulmonary window should approach 0% in the contemporary era with excellent long-term outcomes. Even with associated arch obstruction, overall mortality has improved significantly over time. Tkebuchava and colleagues reported a 92% operative survival and an actuarial survival of 90% at the 10-year follow-up.⁹² In one of the largest series, Hew and colleagues⁷⁸ observed an

early survival of 92% and an actuarial survival of 88% at 10 years. Reviewing a series of 19 patients who underwent repair from 1953 to 1990, van Son and colleagues reported an overall early mortality of 21%.¹⁰⁴ The authors noted that all deaths occurred in patients who underwent repair before 1962. They also observed that the long-term outcome after repair depended on the PVR at the time of closure of the defect. Backer and Mavroudis reported a similar improvement in results.⁷⁷ They reported an operative mortality of 33% when the repair was performed using the technique of closed division of the window. Since changing the operative technique to the transaortic approach, they have seen no mortality. Patients need to be followed for the late development of pulmonary artery stenosis.

SURGICAL MANAGEMENT

Indications and Timing of Surgery

Operative Management

Techniques of Arch Repair

Left Ventricular Outflow Tract Obstruction

Conduct of Surgery and Cardiopulmonary Bypass Support

Hybrid Palliation

RESULTS: SURVIVAL, COMPLICATIONS, AND LATE EVENTS

SUMMARY

Interrupted aortic arch (IAA) is a rare genetic disorder of the cardiovascular system, present in approximately two cases per 100,000 live births and comprising 1.5% of all cases of congenital heart disease. Its hallmark feature is a lack of luminal continuity between the ascending aorta and the descending aorta. In the absence of surgical repair, mortality approaches 75% in the first month of life and 90% by 1 year. Despite tremendous recent progress in the management of complex congenital heart malformations in neonates and infants, the mortality and morbidity associated with surgical management of IAA and the spectrum of associated anomalies remain substantial. Areas of controversy include the choice of single-stage versus multistage repair, the assessment and management of associated obstruction or hypoplasia of the left ventricular outflow tract, and the intraoperative management of cardiopulmonary bypass with or without periods of hypothermic circulatory arrest. Important late-phase events after repair of IAA are related to the potential for development or recurrence of systemic ventricular outflow tract obstruction or aortic arch obstruction, and presurgical and postsurgical abnormalities of neurodevelopmental outcome and their impact on functional status.

HISTORICAL NOTES

The first description of an IAA is attributed to Steidele in 1778.¹ That case involved absence of the aortic isthmus. Absence of the aortic arch segment between the left common carotid artery and the left subclavian artery was described by Seidel in 1818.² Absence of the aortic segment between the innominate artery and the left

common carotid artery was described by Weisman and Kesten in 1948.³ In 1955, Samson and colleagues⁴ performed the first successful surgical repair of IAA in a 3-year-old child. The anatomy included absence of the aortic isthmus, the presence of a patent ductus arteriosus, and two ventricular septal defects (VSDs). In the initial operation, the ductus was divided, and then it was joined to the underside of the proximal left subclavian artery, creating luminal continuity between the ascending aorta and the descending aorta. The VSDs were closed 4 years later. Case reports in the 1960s described interposition of prosthetic grafts to bridge the gap between aortic segments. The first use of turned-down aortic arch branches (left subclavian or left common carotid artery) to achieve end-to-end anastomosis to the descending thoracic aorta was described by Sirak and coworkers in 1968.⁵ One of Sirak's three patients was the first neonate to survive operation. In 1970, Litwin and associates⁶ palliated a neonate with arch interruption and VSD by interposition of a prosthetic tube graft between the proximal main pulmonary artery and the descending thoracic aorta, with banding of the distal main pulmonary artery.

In 1970, Barratt-Boyes and colleagues⁷ described successful repair of IAA and simultaneous correction of intracardiac lesions (VSD and total anomalous pulmonary venous connection). Through a left thoracotomy incision, a 12-mm prosthetic tube graft was connected to the descending thoracic aorta. Next, through a median sternotomy, the proximal end of the conduit was connected to the ascending aorta. Hypothermic circulatory arrest facilitated this anastomosis and the repair of the intracardiac lesions. In 1975, Trusler and Izukawa⁸ were the first to accomplish direct anastomosis of the descending aorta to the ascending aorta and transverse arch (with

excision of all ductal tissue and with no interposition graft), together with VSD closure. The operation was accomplished through a median sternotomy approach, using cardiopulmonary bypass and deep hypothermic circulatory arrest. Primary repair via median sternotomy using continuous cardiopulmonary bypass (without a period of circulatory arrest) was reported by Asou and colleagues in 1996.⁹

In the mid-1960s, Angelo DiGeorge, a pediatric endocrinologist, described the association of hypoparathyroidism (with hypocalcemia), thymic aplasia, cleft lip and palate, and altered immunity (eventually recognized to be the consequence of a T cell abnormality). Several of the patients with this constellation had cardiac anomalies—the most prevalent among DiGeorge's patients was IAA. DiGeorge syndrome and the closely related velocardiofacial syndrome were subsequently found, in the majority of instances, to be related to a chromosomal deletion in the region of 22q11.2.¹⁰⁻¹³ In a prospective evaluation of 251 patients with conotruncal defects who were screened for the presence of a 22q11 deletion, 50% (12 of 24) of patients with IAA were found to have a 22q11 deletion at locus D22S75 (N25).¹⁰

ANATOMY AND NOMENCLATURE

The definition of *interrupted aortic arch* adopted in 2000 by the International Congenital Heart Surgery Nomenclature and Database Project is “loss of luminal continuity between the ascending and descending aorta.”¹⁴ *Absence* of luminal continuity would also be an acceptable description. As a congenital defect, IAA represents a developmental abnormality of the embryologic arch elements. In the instance of left-sided aortic arch, the proximal arch (between the normally positioned innominate artery and the left common carotid artery) is derived from the aortic sac. The distal arch (between the left common carotid artery and the left subclavian artery) is derived from the left fourth embryonic arch, and the isthmus (between the left subclavian artery and the descending thoracic aorta) from the junction of the left sixth embryonic arch (ductus arteriosus) with the left dorsal aorta and the left fourth embryonic arch. It is therefore not surprising that many anatomic variants of IAA are observed, with respect to the site of discontinuity and the sites of origin of the brachiocephalic vessels.

Aberrant origin of the right subclavian artery from the descending thoracic aorta is encountered frequently in some forms of IAA, and rarely in others.¹⁵ It is generally associated with hypoplasia or obstruction of the left ventricular outflow tract (LVOT), as there is less antegrade flow from the left ventricle. Rarely, the site of origin of the right subclavian artery is a persistent right-sided ductus. Interrupted arch can occur with a right aortic arch, with persistence of a right-sided ductus (or bilateral ducts).

In nearly 100% of cases, loss or absence of luminal continuity reflects complete absence of one element of the aortic arch. In rare instances, a fibrous strand connects the ascending aorta and associated arch elements

with the descending aorta. By convention, these rare cases can be referred to as *interrupted aortic arch*, although some would make a distinction and refer to such cases as *atresia* of a particular portion of the arch. Celoria and Patton originally described the most widely accepted classification for IAA in 1959.¹⁶ They divided interrupted arch anomalies into three varieties, based on the site of aortic arch interruption (Fig. 122-1). In the common circumstance of left-sided aortic arch, type A refers to interruption that is distal to the left subclavian artery. In type B, the interruption is between the left common carotid and the left subclavian artery. Finally, in type C, the interruption is between the innominate and left carotid arteries. In a multi-institutional outcome study of 472 patients with IAA by the Congenital Heart Surgeons' Society (CHSS), McCrindle and associates¹⁷ reported that type A was observed in 28% of patients, type B was by far the most common in 70%, and type C was the rarest, seen in only 1%. An aberrant right subclavian artery, originating from the descending aorta and taking a retroesophageal course, is frequently seen in patients with IAA, particularly type B.¹⁵ In other uncommon variations, the aberrant right subclavian artery can originate instead from the right pulmonary artery via a persistent right-sided patent ductus arteriosus (isolated subclavian artery), or the right pulmonary artery can be the vessel that is isolated. These variations have been reported and analyzed, and attempts have been made to expand on the classification system of Celoria to include a description of the origin of the right subclavian artery. The classification system reported by Dische and coworkers in 1975¹⁸ added the subscript 2 to the letter A, B, or C from the Celoria classification when the aberrant right subclavian artery originated from the descending aorta distal to the interruption. Thus, in the system described by Dische, in type A₂ the interruption is distal to the left subclavian artery, and the only major arch vessel taking origin from the aorta distal to the interruption is the aberrant right subclavian artery. Similarly, in type B₂, both carotid arteries arise from the aortic arch proximal to the interruption and both subclavian arteries arise from the aorta distal to the interruption. In 1982, the nomenclature system of Oppenheimer-Dekker and colleagues¹⁹ offered an alternative subclassification also based on the system of Celoria and Patton. This system also includes subdivisions based on the presence of an aberrant right subclavian artery, but here nine types of IAA are classified. Types A, B, and C are determined based on the system of Celoria. No subscript number is used if the right subclavian artery has a normal origin, a subscript 1 is used when the aberrant right subclavian artery originates from the descending aorta, and a subscript 2 is used when the aberrant right subclavian artery arises from the right pulmonary artery via ductal tissue. Most common usage involves the A-B-C system of Celoria together with a specific verbal description of abnormalities of the origin of brachiocephalic vessels, branch pulmonary arteries, or patent ductus arteriosus.

The following is the classification of IAA used in the Diagnostic Long List of the version of the International Paediatric and Congenital Cardiac Code derived from the nomenclature of the International Congenital Heart

FIGURE 122-1 ■ Anatomic types of interrupted aortic arch. **A**, Type A, interruption distal to the left subclavian artery. **B**, Type B, interruption between the left subclavian and left carotid arteries. **C**, Type C, interruption between the left carotid and innominate arteries. Ao, Aorta; DA, ductus arteriosus; IA, innominate artery; LCCA, left common carotid artery; LSA, left subclavian artery; MPA, main pulmonary artery; Prx Desc Ao, proximal descending aorta. (From Jonas RA: Interrupted aortic arch. In Mavroudis C, Backer CL, editors: *Pediatric cardiac surgery*, ed 3, Philadelphia, 2003, Mosby.)

Surgery Nomenclature and Database Project of the European Association for Cardio-Thoracic Surgery and the Society of Thoracic Surgeons²⁰:

1. IAA
2. IAA, type A (interruption distal to the subclavian artery)
3. IAA, type A2 (interruption distal to one subclavian artery, with the only major arch vessel taking origin from the aorta distal to the interruption being an aberrant subclavian artery)
4. IAA, type B (interruption between the carotid and subclavian arteries)
5. IAA, type B2 (interruption between the carotid and subclavian arteries, with both subclavian arteries arising from the aorta distal to the interruption)
6. IAA, type C (interruption between the carotid arteries)
7. IAA, type C2 (interruption between the carotid arteries, with both subclavian arteries arising from the aorta distal to the interruption)

Interrupted aortic arch complexes nearly always have a large VSD (the exception being cases of IAA with aortopulmonary window, of which a majority have an intact ventricular septum). In the setting of IAA with VSD, the VSD can be of any type. Most commonly, it is of the malalignment type. In this circumstance, the conal (outlet) septum is malaligned posteriorly and leftward with respect to the true trabecular septum.^{21,22} The malalignment of the conal septum is associated with varying degrees of subaortic obstruction.²³⁻²⁵ When a malalignment-type VSD is present, the conal septum may be not only misplaced but also hypoplastic. In an echocardiographic study of 53 patients with IAA with VSD, Chin and Jacobs²⁶ found that 43 of 45 patients with type B IAA had VSDs involving maldevelopment of the outflow region. In type A IAA, only four of eight had this type of VSD.²⁶ In the complex of the left side of the heart and the aorta (the left heart–aorta complex), other levels of obstruction that are often associated with IAA include a prominent and obstructive anterolateral muscle of the left ventricle (muscle of Moutaert), aortic valvar stenosis with or without aortic annular hypoplasia, and fibrous or fibromuscular subaortic stenosis.²⁷ IAA can coexist with a wide variety of cardiac lesions, as evidenced by the first report from the CHSS in 1994. Jonas and associates¹⁵ reported that among 250 cases of IAA at participating centers, associated cardiac anomalies included VSD (183 [73%]), truncus arteriosus (25 [10%]), aortopulmonary window (10 [4%]), univentricular atrioventricular connection (9 [4%]), transposition of the great arteries with VSD (8 [3%]), double-outlet right ventricle (5 [2%]), Taussig-Bing anomaly (4 [2%]), complete atrioventricular canal defect (1 [0.4%]), and congenitally corrected transposition of the great arteries (1 [0.4%]). Isolated IAA (without VSD or associated anomalies) was present in only 4 of 250 patients [2%]. More unusual associations have been the subject of individual case reports, including several cases of aortic atresia with IAA and VSD, in which flow to the ascending aorta and thus the coronary arteries depended on flow either through the circle of Willis or through a patent right-sided ductus arteriosus.

PRESENTATION AND PREOPERATIVE MANAGEMENT

During fetal development, the left ventricular output supplies the arterial circulation proximal to the interruption, and right ventricular output supplies arterial circulation distal to the interruption via the left ductus arteriosus. Postnatally, this arrangement continues, with the addition of the pulmonary blood flow to the volume load of the left ventricle. The postnatal pathophysiology of virtually all IAA complexes is predicated on ductal dependency of a portion of the systemic circulation (distal to the interruption), and on a usually large but variable ratio of pulmonary to systemic blood flow (Q_p/Q_s). This ratio is influenced by the anatomic substrate for left-to-right shunting. That may be a VSD alone or a variety of other lesions such as common arterial trunk or aortopulmonary window. In addition, the physiology is influenced by the presence of other obstructive lesions in the left heart–aorta complex. Obstructive or hypoplastic elements of the left heart–aorta complex, alone or in combination with left ventricular dysfunction, may contribute to left-to-right shunting at the atrial level, through either an atrial septal defect or a stretched patent foramen ovale.

Despite the markedly abnormal circulatory arrangement, manifestations of the abnormal physiology may be subtle in the early neonatal period. If ductal patency persists, typical signs of congestive heart failure may emerge in the first few weeks of life, as the pulmonary vascular resistance begins to fall and pulmonary blood flow increases. More typically, and importantly, constriction of the ductus arteriosus can begin and progress any time in the first days or weeks of life. This may be manifest as a mottled or gray appearance of the lower body, and it is accompanied by signs of congestive heart failure (tachypnea, tachycardia, hepatomegaly, and poor feeding) and then of circulatory insufficiency (irritability progressing to lethargy, oliguria, and then metabolic acidosis and profound shock with multiple organ dysfunction and coagulopathy). Early visual evidence of the difference in oxygen saturation between the upper and lower body may be present. Neither this nor differential blood pressure between upper and lower extremities is a constant or particularly useful finding, as either may be influenced by the dynamic variability of the Q_p/Q_s , by diminished cardiac performance, and by abnormal anatomy, including aberrant origin of the right subclavian artery (which, in the setting of IAA type B or type C, results in all four extremities having postductal blood pressures). In the absence of a prenatal diagnosis, approximately half of patients present during the first day of life, and nearly all do within the first 2 weeks of life. In rare instances, persistent patency of the ductus arteriosus is associated with a later presentation.

Echocardiography with color flow mapping is the primary diagnostic study in virtually all cases. When the diagnosis is suspected or established, evaluation as an inpatient in an intensive care setting is advised. Intravenous prostaglandin E_1 should be administered promptly to maintain patency of the ductus arteriosus.²⁸

The need for an arterial line and assisted ventilation can be judged best from the initial arterial blood gas measurement. Unless a period of shock has accompanied ductal constriction, pharmacologic support with catecholamine infusions is rarely indicated. In recent years, the use of milrinone, a phosphodiesterase-3 inhibitor, as a continuous infusion has achieved wide acceptance. It probably contributes to the improvement of myocardial performance that generally occurs with correction of acidosis, and it has the added effect of reducing systemic vascular resistance. Assessment of the presence and degree of secondary organ dysfunction includes laboratory evaluation of metabolic status, serum indicators of renal and hepatic function, and a coagulation profile. Hypocalcemia, a frequent finding, may indicate the presence of DiGeorge syndrome, including the hypoparathyroidism phenotype. Fluorescent *in situ* hybridization can reveal the typical hemizygous 22q11.2 deletion seen in 85% to 95% of patients with DiGeorge syndrome.¹⁰

In most cases, the key features of the anatomy are revealed by a detailed echocardiographic evaluation. A complete study should clarify the site of aortic interruption and the sites of origin of the arch branches. Additional essential information includes the presence and nature of atrial and VSDs, and a detailed assessment of the LVOT. This includes measurement of the dimensions of the subaortic region (including a description of the outlet or conal septum, which may be either thickened or hypoplastic, and which may be posteriorly malaligned, thus narrowing the caliber of the subaortic LVOT), as well as the aortic valve annulus and orifice, and the sinotubular junction and ascending aorta.²⁹ The mitral valve is assessed, including the size of its orifice, its competence, and the nature of the subvalvar apparatus. The size of the left ventricle is measured, and a determination is made regarding whether it extends to the apex of the ventricular mass. Important associated diagnoses to consider include truncus arteriosus communis,³⁰ aortopulmonary window,^{31,32} transposition of the great arteries, and various forms of univentricular atrioventricular connection. A general visual or quantitative assessment of myocardial contractility is made. Although color flow mapping with Doppler studies can be helpful in evaluating some intracardiac obstructive lesions, the definitive echocardiographic assessment is most often made in the setting of a widely patent ductus (and, in most cases, a nonrestrictive interventricular communication). As a result, quantitation of the degree of LVOT obstruction by estimation of a gradient in that region can be misleading.

In some cases, cardiac catheterization with angiography provides important additional information. In particular, it may be helpful in clarifying instances of discontinuous branch pulmonary arteries, anomalous pulmonary venous connections, or transposition of the great arteries (in which case, balloon atrial septotomy may be beneficial). In cases with coexistent aortic atresia, it may help to define the source of coronary blood flow. Another indication for cardiac catheterization is the need to restore and/or maintain patency of the arterial duct. Until recently, maintenance of ductal patency by means

of deployment of an intravascular stent was reserved for unusual circumstances. An example would be the case of late presentation of an infant with IAA type A with VSD, who had a restrictive duct and respiratory syncytial virus pneumonia. Ductal dilation and stenting provided temporary palliation, making it possible to defer arch repair and VSD closure for several weeks to allow resolution of airway inflammation and improvement of pulmonary function. The recent emergence and increasingly widespread adoption of so-called hybrid strategies for initial management of numerous forms of critical heart disease in neonates that share the common feature of ductal dependency of the systemic circulation has added to the surgical armamentarium and increased the therapeutic options for patients with IAA. When such a strategy is applied to neonates with IAA, maintenance of ductal patency (either by stent deployment or by continuous administration of prostaglandin E1) is generally accompanied by bilateral application of pulmonary artery bands to the proximal branch pulmonary arteries to limit pulmonary blood flow.

Increasingly, both computed tomography (CT) and magnetic resonance imaging (MRI) are being used to further clarify the anatomy of complex cardiac anomalies in neonates and infants.³³ Each technology lends itself to three-dimensional reconstruction, which can be helpful in clarifying anatomic details, with particular attention to spatial relationships. CT has the advantage of rapid data acquisition, and in some instances it can be accomplished without general anesthesia. It has the disadvantage of radiation exposure. MRI does not involve radiation exposure, but it generally requires the patient to be anesthetized for the study.

SURGICAL MANAGEMENT

Indications and Timing of Surgery

Interrupted aortic arch is incompatible with life without patency of the ductus arteriosus or an alternative pathway for perfusion of the lower body. Before the availability of prostaglandins, the diagnosis of IAA was a surgical emergency. Most often, neonates were in poor condition, with a closing ductus, and resuscitative measures had little efficacy. Patients had to be taken to surgery in poor condition. Emergent palliative operations were performed under less than ideal conditions, and they often yielded less than optimal outcomes. In the current era, restoration of ductal patency after infusion of prostaglandin E₁ is generally accomplished, facilitating resuscitation in an intensive care unit.²⁸ Recovery of renal and hepatic function usually follows correction of acidosis and optimization of respiratory parameters and fluid and metabolic status. This then facilitates stabilization and assessment of neurologic status, and recovery or correction of coagulation disorders. Genetic evaluation can be initiated, and meaningful family education and counseling can occur before surgery is undertaken. An operation is usually indicated as soon as these preliminary objectives have been achieved, as there is no definitive medical therapy for IAA.

Operative Management

As noted, the history of surgery for IAA began during an era when the use of cardiopulmonary bypass to accomplish repair of intracardiac defects in infants and neonates was a theoretical goal for the future rather than a therapeutic reality. As a result, most early arch repairs were closed-heart (i.e., nonbypass) procedures.^{6,34} Arch repair was accomplished using an interposition graft or a brachiocephalic vessel turn-down, either in isolation or in combination with banding of the pulmonary artery. In most instances, repair of the VSD (with removal of the pulmonary artery band) would be undertaken some months later. Even after the introduction and successful achievement of one-stage repair of IAA and VSD closure, both via median sternotomy with cardiopulmonary bypass and hypothermic circulatory arrest, there persisted at many centers a bias favoring a staged approach to IAA with VSD or other more complex cardiac anatomy.³⁵ In 1997, Mainwaring and Lamberti reported on their 10-year experience with a two-stage approach to repair IAA type B with VSD.³⁶ Twenty-six of 27 patients survived stage 1 (arch repair with interposition graft). Twenty-two of 25 patients who underwent subsequent VSD closure were long-term survivors. Freedom from reoperation for arch graft enlargement was 86% at 3 years and 55% at 5 years.

In 1994, the CHSS published a report of their first multi-institutional outcome study of patients with IAA and VSD.¹⁵ Patients were enrolled as neonates between 1987 and 1992, and 173 patients underwent reparative surgery. The initial procedure consisted of arch repair and VSD closure (one stage) in 116 (67%), arch repair and banding of the pulmonary trunk in 40, and only repair of the arch interruption in 17. Thus, one-stage repair was chosen in 67% of cases, with intent to undertake two-stage repair in 33%. In the past two decades, single-stage repair of IAA and intracardiac defects has gained wide acceptance. At most centers, it is the usual or routine technique used, with a two-stage approach being reserved for specific uncommon circumstances.³⁷⁻⁴¹

Techniques of Arch Repair

An optimal method of arch repair would be one that could be performed safely and reproducibly in neonates, with minimal likelihood of stenosis in the short or long term. Thus, it would result in normal growth of all aortic segments including the anastomotic area. Ideally, it would not require use or division of any of the principal brachiocephalic vessels. In the traditional multistage approach, a synthetic tube graft was interposed between the proximal (ascending) and distal (descending) aortic elements. Although this can generally be accomplished without cardiopulmonary bypass support through either a lateral or an anterior approach, the certainty that the graft will not grow with the patient ensures an absolute requirement for arch reintervention in all survivors.⁴²⁻⁴⁴ That reintervention can consist of graft replacement in situ, augmentation in situ, or extra-anatomic placement of an additional graft. An alternative technique that has been used in both one-stage and two-stage strategies is

the use of a turned-down brachiocephalic artery (carotid or subclavian artery) that is anastomosed to the descending aorta. Monroe and colleagues⁴⁵ published a small series demonstrating satisfactory growth of the arch elements and anastomotic region in the majority of patients at follow-up of 8 to 19 years. More recently, John Brown and associates⁴⁶ reviewed their experience with 47 patients who underwent repair of IAA by means of left carotid artery turn-down. Approximately one third of patients underwent subsequent reinterventions on the arch. The authors claimed as advantages the reduced exposure to circulatory arrest and cardiopulmonary bypass in the newborn period and low incidence of bronchial compression by the reconstructed arch.

In the current era, the approach most often used is a one-stage approach entailing direct anastomosis between the ascending aorta and the descending aorta. This approach involves extensive mobilization of both proximal and distal elements. Several centers have reported excellent early outcomes with the technique of end-to-side anastomosis of the descending thoracic aorta either to the ascending aorta or to the ascending aorta and the underside of the proximal aortic arch.^{41,47-49} Patch augmentation of the anastomosis of the proximal and distal aortic segments was described by Norwood in 1990, and intermediate-term results were reported by Jacobs and Norwood in 1995.⁵⁰ This technique is intended to reduce tension on the anastomosis, to enlarge the connection between segments, and to address hypoplasia of the ascending aorta, which is particularly common in IAA types B and C.^{22,25} In addition, the use of patch augmentation generally obviates the need to divide either the left subclavian artery or an anomalous right subclavian artery to bring the elements of the arch together. It also lessens the likelihood of left bronchial compression, which can complicate some repairs of IAA.⁵¹ We have used cryopreserved pulmonary artery homograft tissue for the patch material. Successful use of other patch materials has been reported, including pulmonary artery autograft tissue.⁵²

The 1994 CHSS report of outcomes in patients with IAA and VSD included an important observation concerning the potential benefit of patch augmentation of the amalgamation of the ascending and descending aorta in patients with additional levels of obstruction or hypoplasia in the left heart-aorta complex.¹⁵ Multivariable analysis identified subaortic or annular narrowing as incremental risk factors for death after repair (Fig. 122-2). The report by Jonas and associates¹⁵ concluded, "In the 20% of patients in whom obstruction existed elsewhere in the left heart-aorta complex, the percent survival was highest among those undergoing ascending aorta/arch augmentation." More recently, in a CHSS analysis of intermediate- and long-term outcomes of an expanded cohort of 472 neonates with IAA, McCrindle and associates¹⁷ reported that reintervention was more likely for those who had IAA repair by a method other than direct anastomosis with patch augmentation. In a single institution study from Marie Lannelongue Hospital in 2002, Roussin and associates⁵³ described excellent results with the incorporation of a pulmonary artery autograft patch into the aortic arch reconstruction. Among 20 patients who underwent repair of IAA with

FIGURE 122-2 ■ Data from the Congenital Heart Surgeons' Society (CHSS) study of outcomes in neonates with interrupted aortic arch (IAA) and ventricular septal defect (VSD). Nomogram of a specific solution of a multivariable equation demonstrating the risk-adjusted effect of the measured diameter of the left ventricular (LV)-aortic junction. The value of 3.1 kg was entered for the birth weight, 7 days for age at repair, type B for IAA, and conoventricular for the VSD. Arrowheads indicate points of evident difference, from right to left. CL, Confidence limits. (From Jonas RA, Quaegebeur JM, Kirklin JW, et al: Outcomes in patients with interrupted aortic arch and ventricular septal defect. A multiinstitutional study. Congenital Heart Surgeons Society. *J Thorac Cardiovasc Surg* 107:1099-1109, 1994.)

pulmonary autograft patch aortoplasty, actuarial freedom from interventions for recurrent arch obstruction was 100% at median follow-up of 29 months.

Left Ventricular Outflow Tract Obstruction

Estimates of the incidence of occurrence of important LVOT obstruction in the setting of IAA vary considerably^{24,34,54-59} because of the inability to measure an outflow tract gradient accurately in the setting of a large VSD and a patent ductus, and also because there currently is no consensus on the morphologic criteria or threshold measurements that should be used to assign such a diagnosis. Narrowing of the subaortic region can be mild to severe as a consequence of deviation of the conal septum into the LVOT in the setting of IAA with malalignment-type VSD. In addition, as mentioned, posterior deviation of the conal septum can contribute to LVOT obstruction even when the conal septum is hypoplastic and entirely fibrous. In these cases, there is generally hypoplasia of the aortic annulus. As there is no option of resecting muscle to enlarge the subaortic region, the need to anchor the top of the VSD patch to this fibrous rim not only results in a narrow subaortic region; it can also result in fixation of a portion of the aortic annulus, preventing subsequent normal growth. In the 1994 report of the first multi-institutional study of IAA by the CHSS, subaortic or annular narrowing was predictive of mortality after repair.¹⁵ The techniques used by participating surgeons to address subaortic narrowing included partial resection of obstructing muscle in the LVOT (myotomy or myectomy) and techniques to bypass the narrowed systemic

ventricular outflow tract. In the analysis, these were combined together as Damus-Kaye-Stansel procedures. The analysis led to an interesting but unsatisfying conclusion. Investigators reported, "Procedural risk factors for death after repair were (1) repair without concomitant procedures in patients with other important levels of obstruction in the left heart-aorta complex, (2) a Damus-Kaye-Stansel anastomosis, and (3) subaortic myotomy or myectomy in the face of subaortic narrowing. One-stage repair plus ascending aorta/arch augmentation had the highest predicted time-related survival in the 20% of patients with IAA and one or more coexisting levels of obstruction in the left heart-aorta complex, as did initial repair without or with aorta/arch augmentation in the 80% without these." The troubling inference, of course, was that the presence of obstructing lesions in the left heart-aorta complex was associated with an increased likelihood of death after repair, but that specific procedures directed at these obstructions (other than patch augmentation of the arch repair) did not (in this study) reduce the risk of mortality.

It is important to recognize that not all procedures to bypass subaortic obstruction are the same. The first report of such a procedure was by Yasui and colleagues in 1987.⁶⁰ The operation consisted of ligation of the patent ductus arteriosus, restoration of aortic continuity with an 8-mm polytetrafluoroethylene graft, placement of an internal patch to tunnel all left ventricular blood from the left ventricle through the VSD into the pulmonary artery, transection of the main pulmonary artery, anastomosis between the proximal pulmonary artery and the ascending aorta, and interposition of a valved conduit between the right ventricle and the distal pulmonary artery. Others adapted the type of aortopulmonary amalgamation with arch augmentation developed by Norwood to cases of IAA with severe LVOT obstruction. Jacobs and Norwood⁵⁰ reported a series of nine patients treated with arch repair, aortopulmonary amalgamation, and homograft patch augmentation of the entire aortic reconstruction (Fig. 122-3). Seven patients received aortopulmonary shunts, and two patients underwent one-stage biventricular repair with tunneling of left ventricular outflow through the VSD to the pulmonary valve, and establishment of continuity between the right ventricle and the confluence of branch pulmonary arteries using a valved homograft. There was one hospital mortality.

As part of the aforementioned study by Jacobs and associates,⁵⁰ Chin undertook a detailed retrospective analysis of all of the preoperative echocardiography studies. One important observation was that when the dimensions of the subaortic region were measured in images obtained from four standard echocardiographic windows, the values for a given patient varied considerably from one view to another. In most instances, the smallest dimensions were measured using the subcostal left anterior oblique window. Another observation was that nearly half of the patients in this series with narrowing of the subaortic region also had a bicuspid aortic valve. Investigators from other centers have also reported encouraging surgical results using a technical approach that combines features of the Norwood procedure with the Rastelli operation. In 2001, Erez and associates⁶¹

FIGURE 122-3 ■ A technique for repair of interrupted aortic arch with a severe degree of left ventricular outflow obstruction. The repair incorporates transection of the main pulmonary artery, proximal main pulmonary artery–ascending aortic amalgamation, anastomosis of proximal and distal aortic elements, and pulmonary homograft patch augmentation of the reconstructed arch. (From Jacobs ML, Chin AJ, Rychik J, et al: Interrupted aortic arch. Impact of subaortic stenosis on management and outcome. *Circulation* 92[9 suppl]:II128–II131, 1995.)

reported a series of 12 patients with IAA and LVOT obstruction treated initially with a Norwood procedure. The mean z-value for the subaortic diameter was -5 ± 1.7 . There were no hospital deaths. At the time of the report, six patients had gone on to successful biventricular repair. Therefore, Norwood's technique of aortopulmonary amalgamation, modified to include augmentation of the reconstructed aortic arch, can be applied to patients with IAA and LVOT obstruction to accomplish biventricular repair in one stage at the time of initial arch repair, or as part of a staged approach leading either to biventricular repair or to univentricular palliation.

Others have reported success with less radical procedures for management of IAA with LVOT obstruction. In 1993, Bove and associates⁵⁴ described an approach to LVOT enlargement in patients with IAA and LVOT obstruction. At operation, the posteriorly displaced infundibular septum was partially removed through a right atrial approach by resecting the superior margin of the VSD up to the aortic annulus. The resulting enlarged VSD was then closed with a patch to widen the subaortic

FIGURE 122-4 ■ Alternative techniques for closure of the ventricular septal defect (VSD) in the setting of interrupted aortic arch with malalignment type VSD. **A**, Preoperative anatomy, showing displacement of the malaligned conal septum into the left ventricular outflow tract. **B**, Patch closure of the VSD after partial resection of the conal septum. **C**, Patch closure of the VSD as advocated by Luciani and associates.⁶³ The upper end of the VSD patch is placed on the left side of the septum to deflect the conal septum anteriorly and away from the subaortic area. (From Tchervenkov CI, Jacobs JP, Sharma K, et al: Interrupted aortic arch: surgical decision making. *Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu* 92–102, 2005.)

area. In each patient, the aortic arch was repaired by direct anastomosis. All three patients survived operation. More recently, investigators from the same center analyzed a group of 27 patients with IAA and malalignment type VSD.⁶² Fifteen patients with the smallest subaortic areas underwent myectomy or myotomy of the infundibular septum concomitant with IAA and VSD repair. Two hospital deaths occurred in this group. No late deaths occurred. Six patients required nine reoperations for LVOT obstruction. Five patients underwent resection of a new subaortic membrane. Only one patient had recurrent muscular LVOT obstruction. Three patients required a second reoperation, primarily related to aortic valve stenosis. The authors concluded that this approach to subaortic narrowing was effective at preventing or prolonging the interval to reinterventions for recurrent LVOT obstruction.

In 1997, Luciani and associates⁶³ described a novel approach to one-stage repair of IAA, VSD, and subaortic obstruction. In nine neonates, the VSD was closed with either a transpulmonary (seven patients) or crossatrial (two patients) approach. Without resection of the conal septum, the upper end of the ventricular septal patch was placed on the left side of the septum to deflect the conal septum anteriorly and away from the subaortic area. The authors emphasized the importance of not oversizing the VSD patch, so as to keep it from bulging into the LVOT (Fig. 122-4). It is noteworthy that the degree of severity of subaortic stenosis according to preoperative echocardiography (mean ratio of subaortic to descending aortic diameter, 0.63 ± 0.08) was somewhat less in patients in this series than in those judged to have significant LVOT obstruction in some other series.

Schreiber and associates⁴⁰ recently reported a single institution's 20-year experience with 94 patients diagnosed with IAA. Thirteen patients were considered to have significant LVOT obstruction. Procedures directed at subaortic obstruction included myomectomy,

homograft aortic root replacement, and the Norwood procedure. A preoperative diagnosis of LVOT obstruction was found to be a significant predictor of early and late mortality. More recently, several groups have described success with Ross-Konno procedures for IAA with LVOT obstruction either as a primary repair or, more frequently, as a reintervention in the setting of recurrent LVOT obstruction.^{64–66}

Not all investigators agree that LVOT obstruction is a risk factor for mortality after repair or for the need for reoperation. In 1999, Fulton and associates reported outcomes of a series of 72 patients who underwent repair of IAA between 1985 and 1997.⁵⁵ Thirty-six patients (50%) had LVOT obstruction by one or more of the authors' multiple criteria: (1) dimensions of the LVOT smaller than the mean value minus 1 standard deviation (indexed to body surface area), (2) presence of a gradient of greater than 10 mm Hg across the LVOT, measured by Doppler echocardiography or at cardiac catheterization, (3) posterior deviation of the conal septum into the LVOT, and (4) presence of obstructing tissue in the subaortic area. Patients with LVOT obstruction had comparable survival rates to those without obstruction. At 10 years, the difference in freedom from reoperation did not significantly differ between groups. However, of 36 patients judged to have LVOT obstruction, only 15 (42%) were believed to have obstruction that was severe enough to require surgical treatment at the initial operation. This is an example of the difficulty encountered in interpreting various investigators' recommendations in regard to LVOT obstruction in the setting of IAA. There is no consensus definition, and the criteria vary from one study to another. Unlike Fulton and associates, authors of many outcome studies include in the LVOT obstruction group only those patients for whom the initial operative approach is altered to address the problem specifically.

Tchervenkov and associates⁶⁷ recently undertook a review of published experiences with management of

IAA with LVOT obstruction and offered the following guidelines:

- If the diameter of the LVOT is smaller in millimeters than the baby's weight in kilograms, then survival with a conservative approach is unlikely. For example, for a 3-kg baby, survival is unlikely if the LVOT is smaller than 3 mm and the LVOT is not addressed.
- If the LVOT diameter is greater than the baby's weight (in kilograms) plus 2 mm (e.g., if weight is 3 kg, then diameter greater than 5 mm), survival without significant LVOT obstruction is likely.
- Between these two numbers is a gray zone, where, although survival may be possible, it is likely that significant residual LVOT obstruction will exist.

These general guidelines were based on impressions drawn by Tchervenkov and his coauthors⁶⁷ from their review of other surgeons' series and from personal experience. It is important to recognize that they are not derived from a statistical analysis of any actual data set.

The foregoing discussion addresses the questions of the potential effects of LVOT obstruction on survival after repair, and the primary surgical approaches to the management of moderate to severe LVOT obstruction. Important information is also available regarding the effects of LVOT obstruction on the need for subsequent interventions and long-term survival after repair. Geva and associates⁶⁸ undertook a retrospective study of 37 patients who had undergone repair of IAA, and they investigated the relationship between preoperative morphology and postoperative development of LVOT obstruction. They found a correlation between a preoperative indexed LVOT cross-sectional area of less than 0.7 cm²/m² and subsequent development of LVOT obstruction. They used a threshold value of a gradient of 20 mm Hg to define the presence of LVOT obstruction. This value is lower than has been applied by some others. Apfel and associates⁶⁹ used a gradient of 40 mm Hg as their definition of postoperative LVOT obstruction. They reviewed the preoperative echocardiograms and the postoperative clinical course and echocardiograms of 23 consecutive patients who underwent primary repair of IAA without a surgical modification aimed at widening of the subaortic region. Nine patients (39%) went on to develop significant LVOT obstruction (seven of them by 1 month, eight by 2 months, and all nine by 1 year). On retrospective analysis of the preoperative echocardiograms, the indexed cross-sectional area of the LVOT, the subaortic diameter index, and the subaortic diameter z-score were all significantly smaller in those requiring re-intervention ($P < 0.04$, $P < 0.05$, $P < 0.05$, respectively). Indexed cross-sectional area had the least reproducibility, and subaortic diameter index had the most. The authors concluded that most patients who develop significant LVOT obstruction after repair of IAA do so early after operation. Although subaortic indexed cross-sectional area was the most sensitive predictor of LVOT obstruction after primary repair, other, simpler standardized measurements of the subaortic diameter were comparably predictive and had better reproducibility.

In 2010, Hirata and associates⁷⁰ reported an analysis of outcomes of 38 patients who underwent single-stage

complete repair at Morgan Stanley Children's Hospital of New York. Using a minor modification of the criteria described by Tchervenkov,⁶⁷ they classified patients into two groups. If the aortic annulus was greater than the patient's weight (in kilograms) plus 1.5 mm, the patient was included in group "large," and if the aortic annulus was equal to or smaller than the patient's weight plus 1.5 mm, the patient was included in group "small." The average follow-up was 7.9 ± 4.2 years. Among the patients with small aortic annulus ($n = 12$), there was one hospital death and six reoperations for LVOT obstruction, and one late death. There was only one reoperation for LVOT obstruction among the patients with larger aortic annulus ($n = 26$; $P < 0.001$).

In 2013, Chen and associates⁷¹ at Boston Children's Hospital reported their analysis of predictors of reintervention following neonatal repair of IAA with VSD. Retrospective data were collected on neonates with IAA with VSD who underwent single-stage repair from 1995 to 2009. Sixteen patients (23%) required surgical or percutaneous reintervention for clinically significant postoperative LVOT obstruction. By univariate analysis, LVOT cross-sectional area, LVOT diameter, and aortic root size (all from two-dimensional echocardiography before neonatal repair) were predictors of reintervention. On multivariable linear regression model, aortic root size (from the parasternal long-axis view in end systole) was identified as an independent predictor of reintervention. In identifying an aortic root size inflection point, patients with an aortic root size less than 6.5 mm were at greater risk for reintervention compared with patients with a root size greater than 6.5 mm (reintervention rate 44% and 12%, respectively).

The procedures used to address residual or recurrent LVOT obstruction after initial repair of IAA are numerous, and the choice depends on the specific morphology encountered. Fibrous or fibromembranous subaortic stenosis can generally be approached through the aortic valve. Enucleation of fibrous tissue from the LVOT may need to be preceded by aortic valvotomy (if valvar stenosis is present) and accompanied by myotomy and myectomy of obstructing muscle in the LVOT. Long-segment fibromuscular subaortic stenosis, if present, is best managed with extended ventricular septoplasty (the modified Konno procedure). Working through a right ventricular infundibular incision, an incision is made in the ventricular septum, generally through the area of the previously closed VSD. This incision is carefully monitored by periodic visualization through an aortotomy, looking down through the aortic valve. From the right ventricular approach, the septal incision is extended into the LVOT and is carried up to within a few millimeters of the aortic valve annulus. A patch is then placed on the right ventricular aspect of the surgically enlarged VSD. The infundibulotomy is closed either directly or with a patch. If significant aortic annular hypoplasia is an element of complex LVOT obstruction, then a conventional Konno procedure (with aortic valve prosthesis) or a Ross-Konno procedure is performed. The latter involves an anterior incision through the aortic annulus and into the ventricular septum, and pulmonary autograft replacement of the aortic valve, with the use of a patch or of

infundibular muscle attached to the autograft to enlarge the LVOT.⁶⁵ Finally, the placement of a valved conduit from the left ventricular apex to the descending thoracic aorta remains an option,⁴⁴ although it is rarely used.

Conduct of Surgery and Cardiopulmonary Bypass Support

The availability of prostaglandin and the resultant opportunity to stabilize the condition of most patients before surgery, together with refinements in the technology and conduct of cardiopulmonary bypass and the use of deep hypothermia with circulatory arrest, led to the widespread acceptance and performance of one-stage repair of IAA and associated intracardiac defects. Operative strategies based on preliminary surface cooling and core cooling on cardiopulmonary bypass, followed by a period of circulatory arrest and then reperfusion and rewarming on bypass, remain in widespread use today. Essential features include perfusion inflow through the main pulmonary trunk, with temporary tourniquet occlusion of the branch pulmonary arteries. Although adequate cooling of the brain (as reflected by appropriately falling nasopharyngeal and tympanic temperature) can generally be accomplished in this fashion, many surgeons routinely place an additional small (6- or 8-French) inflow cannula in the ascending aorta. The two perfusion cannulas are set up in advance, joined by a Y-connector. Cannulation of the ascending aorta must be undertaken with great care, as the vessel is particularly small in the setting of IAA type B or C (Fig. 122-5). The purse-string suture through which the aortic perfusion cannula will be inserted should be placed so that it will be just opposite the anastomosis that will be made; it is generally slightly more than half-way between the aortic valve and the origin of the first branch vessel (innominate or right common carotid artery) and toward the right side of the ascending aorta. Alternatively, the need for an aortic perfusion cannula can be assessed by addition of cerebral monitoring with near infrared spectroscopy to supplement temperature monitoring.

Regardless of perfusion technique, all repairs of IAA are facilitated by extensive mobilization of the ascending aorta and each of its branches, as well as the descending aorta and its branches. In general, this can be accomplished during the initial cooling phase of cardiopulmonary bypass. Extensive manipulation and dissection before the initiation of bypass can sometimes upset the already fragile hemodynamic state. If hypothermic circulatory arrest is anticipated, suture tourniquets are loosely placed around each of the aortic arch branches; they are not snugged down and occluded until immediately before circulatory arrest. Venous return to the pump oxygenator is either by single cannula in the right atrium (in which case, closure of a VSD is accomplished either during the period of circulatory arrest or by a transpulmonary approach while on cardiopulmonary bypass) or by means of bicaval cannulation (in which case, the intracardiac portion of the repair can be accomplished on bypass, either before or after the arch repair). If single cannulation of the right atrium with transpulmonary closure of the VSD is planned, intracardiac visualization can be

FIGURE 122-5 ■ Systemic perfusion via cannulation of both the main pulmonary trunk and the diminutive ascending aorta. Tourniquets are used to occlude the right and left branch pulmonary arteries during perfusion, and to occlude the aortic arch branches only during a period of hypothermic circulatory arrest. (From Luciani GB, Ackerman RJ, Chang AC, et al: One-stage repair of interrupted aortic arch, ventricular septal defect, and subaortic obstruction in the neonate: A novel approach. *J Thorac Cardiovasc Surg* 111:348–358, 1996.)

enhanced with the use of vacuum-assisted venous drainage. Although a single dose of antegrade cardioplegia suffices in most cases, this can be replaced or supplemented with single or multiple doses of retrograde cardioplegia via the coronary sinus. If the total duration of hypothermic circulatory arrest is anticipated to exceed 35 to 40 minutes, a brief period of hypothermic reperfusion can be accomplished immediately after completion of the arch reconstruction, with the remainder of the repair being accomplished during a second period of circulatory arrest.

Many surgeons have been pleased with the results of direct end-to-side anastomosis of the descending aorta to the left lateral aspect of the ascending aorta (Fig. 122-6), or to the left side of the distal ascending aorta and the underside of the proximal arch (in IAA type A). We and others⁷² have generally preferred to create an anastomosis that is augmented with a gusset of homograft vascular patch material (Fig. 122-7). To accomplish this, an incision is made in the left lateral aspect of the ascending aorta beginning a few millimeters above the sinotubular junction. The incision is carried onto the left side of the most distal arch branch associated with the ascending aorta. (To facilitate this, the occluding suture tourniquet must be placed as far distally as possible.) After ligation of the pulmonary artery end of the ductus, the ductus is divided, and all ductal tissue associated with the

FIGURE 122-6 ■ Direct end-to-side anastomosis of the descending aorta to the left lateral aspect of the ascending aorta. A vascular clamp is applied across the descending thoracic aorta to facilitate positioning of this segment for the anastomosis. (From Luciani GB, Ackerman RJ, Chang AC, et al: One-stage repair of interrupted aortic arch, ventricular septal defect, and subaortic obstruction in the neonate: A novel approach. *J Thorac Cardiovasc Surg* 111:348–358, 1996.)

FIGURE 122-7 ■ Our preferred technique for interrupted aortic arch repair with homograft vascular patch augmentation of the aortic anastomosis. (From Jacobs ML, Chin AJ, Rychik J, et al: Interrupted aortic arch. Impact of subaortic stenosis on management and outcome. *Circulation* 92[9 suppl]:II128–II131, 1995.)

descending thoracic aorta is excised. The resulting opening into the descending aorta is extended a few millimeters along the right side of the first branch associated with the descending aorta (in IAA type B, this is the left subclavian artery). An incision is also carried down from the opening into the descending aorta, along the medial aspect of the aorta, to a point approximately 1 cm below the opening of the ductus into the aorta, as is done in a stage I Norwood procedure. Direct anastomosis of the proximal and distal aortic elements along their greater curvature is accomplished, including side-to-side amalgamation of the last aortic branch associated with the proximal segment and the first branch associated with the distal segment. The entire aortic arch is then augmented along its lesser curvature with a homograft vascular patch, beginning distally on the descending thoracic aorta. Once the arch reconstruction has been completed, the aorta is cannulated through a pursestring suture that, ideally, is situated on the right side of the augmented ascending aorta, several millimeters distal to the most proximal extent of the homograft patch. This minimizes the likelihood of aortic narrowing resulting when tying down the pursestring suture after decannulation. Perfusion can be resumed at this time, or alternatively the VSD can be closed before resumption of cardiopulmonary bypass. The technique of homograft patch augmentation of the aortic anastomosis has proved particularly useful in the setting of repair of truncus arteriosus with IAA.⁷³

These methods have yielded satisfactory outcomes, and they remain in use at many centers. Recently, however, techniques allowing continuous cerebral perfusion have gained favor, because they minimize the use or duration of hypothermic circulatory arrest.^{9,74,75} Clinical studies comparing neurodevelopmental outcomes in patients undergoing arch repair with continuous cerebral perfusion to those with hypothermic circulatory arrest have, for the most part, been in the setting of stage I Norwood procedures, and the results at 1 year are similar between groups. Issues pertaining to optimal temperature, rates of flow, and pH strategy remain to be resolved. Nonetheless, the idea of continuous cerebral perfusion is appealing to many surgeons, and its use is increasing steadily.

Continuous antegrade cerebral perfusion is accomplished either by advancing a small aortic perfusion cannula into the right common carotid artery⁷⁵ or by direct cannulation of the innominate artery (with a 6 or 8 Fr cannula),⁷⁴ or by anastomosis of a 4- or 5-mm polytetrafluoroethylene graft to the innominate artery, into which a perfusion cannula is placed with care to exclude air. A second perfusion cannula is placed in the main pulmonary artery (Fig. 122-8). After hypothermic bypass is established and the target core temperature is reached, the perfusion cannula in the pulmonary artery is clamped and removed. Flow is reduced and maintained at a level of 40 to 70 mL/kg/min. The ductus is suture-ligated at the pulmonary artery end. A small vascular clamp is placed on the descending aorta approximately 1 cm distal to the point of insertion of the ductus. The left subclavian artery (and an aberrant right subclavian artery if present) is occluded temporarily with a small removable neurovascular clip. The ductus is divided, and

FIGURE 122-8 ■ A perfusion arrangement for interrupted aortic arch repair that facilitates arch anastomosis during a period of selective antegrade cerebral perfusion. This arrangement, used by Malhotra and Hanley⁷⁴ and others, includes direct cannulation of the innominate artery and the main pulmonary trunk. The dotted line indicates proposed sites for incision in the ascending aorta and for transection of the ductus arteriosus. (From Coarctation of the aorta and interrupted aortic arch. In Kouchoykos NT, Blackstone EH, Doty DB, Hanley FH, Karp RB, editors: *Kirklin and Barratt-Boyes' cardiac surgery*, ed 3, Philadelphia, 2003, Churchill Livingstone, pp 1315–1375.)

any ductal tissue associated with the descending thoracic aorta is excised. The vascular clamp on the descending aorta is required in this circumstance to prevent back-bleeding, but it is also useful under conditions of circulatory arrest to aid in manipulation of the distal aortic segment. If direct end-to-side anastomosis of the descending aorta to the ascending aorta is planned, a small straight vascular clamp is placed across the arch of the aorta at the base of the innominate artery and the left common carotid artery (Fig. 122-9), maintaining luminal continuity and facilitating perfusion of both branches.⁷⁴ The end-to-side anastomosis is accomplished proximal to this point (Fig. 122-10). Cardioplegia solution is administered in antegrade fashion into the ascending aorta. If patch augmentation of the anastomosis is planned, the straight vascular clamp is applied proximal to the perfusion cannula at the base of the innominate artery. The left common carotid (in addition to any more distal branches associated with the ascending aorta) is gently occluded somewhat distally, with either a suture tourniquet or a neurovascular clip. In this way, the anastomosis of the proximal and distal aortic segments can include side-to-side amalgamation of most proximal portions of the last aortic branch associated with the ascending aorta, and the first branch associated with the descending aorta. The anastomosis is augmented along its lesser curvature with a gusset of cryopreserved homograft vascular patch material. When this technique is used, it is rarely necessary to ligate and divide a left or an aberrant right subclavian artery. All tourniquets and other occluding devices are removed from the aorta and its branches. Full flow (or systemic perfusion at a level appropriate to the core temperature) is resumed. An additional dose of antegrade cardioplegia is given if so desired, and the intracardiac repair is undertaken. The VSD is closed using a

transpulmonary or transatrial approach, and an atrial septal defect or stretched foramen is approached through the right atrium. After rewarming, separation from bypass is accomplished.

Hybrid Palliation

In selected cases, a decision may be made to delay definitive repair of the interrupted arch and associated intracardiac defects, in favor of a course of treatment based on initial stabilization of the circulation by a combination of maneuvers that restore and maintain patency of the arterial duct and that limit pulmonary blood flow. Based on the same principles as the so-called hybrid strategy for initial palliation of hypoplastic left heart syndrome, this generally involves a median sternotomy approach for bilateral application of bands to the right and left branch pulmonary arteries and either prolonged continuous infusion of prostaglandin E1 or transpulmonary artery deployment of an intravascular stent in the arterial duct.^{76,77} This alternative strategy is generally reserved for instances of rescue therapy for neonates with shock and secondary organ dysfunction in the setting of ductal constriction or with significant infection. It can also be used when temporary delay of definitive repair requiring cardiopulmonary bypass is judged to be advantageous, which might include instances of extreme prematurity or of neurologic complications such as intraventricular hemorrhage.

RESULTS: SURVIVAL, COMPLICATIONS, AND LATE EVENTS

In general, single-institution series describing results of surgical management of IAA reflect the challenge and complexity of this group of lesions, but they offer encouraging results that in the aggregate suggest that a good deal of progress has been made over the past 2 decades.^{41,42,46,55} Several institutions describe operative survival on the order of 90%. In individual series, the incidence of reintervention during follow-up varies from as little as 10% to greater than 50%.* In the Congenital Heart Surgery Database of the Society of Thoracic Surgeons,⁷⁹ the mortality at discharge from hospital after IAA repair in the 4-year interval from 2004 through 2007 is 8.9% (32/359).

Multi-institutional outcome studies provide a broader overview of experience and offer the opportunity to undertake risk analysis on a large set. The CHSS initiated its first prospective multi-institutional outcome study of patients with IAA in 1987, with patient enrollment at 30 participating institutions. In 1994, the first CHSS report, by Jonas and associates,¹⁵ analyzed the outcomes from management of 183 neonates with IAA and VSD entering the study between 1987 and 1992. Nine patients died without any surgery. Among the remaining 174, survival rates at 1 month and 1, 3, and 4 years after repair were 73%, 65%, 63%, and 63%, respectively. The risk factors

for death were low birth weight, younger age at repair, interrupted arch type B, outlet and trabecular VSDs, smaller size of the VSD, and subaortic narrowing.

Echocardiographically measured dimensions at all levels of the left heart–aorta complex were small. As previously noted, procedural risk factors for death after repair were (1) repair without concomitant procedures in patients with other important levels of obstruction in the left heart–aorta complex, (2) a Damus-Kaye-Stansel anastomosis, and (3) subaortic myotomy or myectomy in the face of subaortic narrowing. One-stage repair plus ascending aorta or arch augmentation had the highest predicted time-related survival in the 20% of patients with IAA and one or more coexisting levels of obstruction in the left heart–aorta complex, as did initial repair without or with aorta or arch augmentation in the 80% without these. Only 26% of patients in whom a lateral thoracotomy was used (as in most initial repairs in which the VSD was not closed) had a direct anastomosis, in contrast to 92% of those in whom a median sternotomy with a one-stage repair was performed. Among the 57 patients who did not have the VSD closed at the initial procedure, essentially all who survived had it closed within 36 months of the initial repair. The peak rate of VSD closure by a subsequent procedure was highest during the first month after the initial procedure, suggesting that the untreated VSD was not being well tolerated and that a one-stage repair at the initial procedure might have been preferable. By the time the analysis was undertaken, 20 patients had undergone reintervention for arch obstruction. In nine patients, the procedure was percutaneous balloon dilation. The peak of the hazard function for this reintervention was approximately 4 months after the initial repair. Fifteen of the 116 patients undergoing one-stage repair had a first reintervention for one or more coexisting obstructive lesions in the left heart–aorta complex (e.g., LVOT obstruction). Freedom from such reinterventions was only 77% at 3 years. This unique multi-institutional study revealed that optimal management of coexisting obstructive left heart lesions in association with IAA remained an unresolved challenge at the time. It also pointed out the ongoing risks of recurrent arch obstruction and LVOT obstruction in survivors of neonatal repair. These findings encouraged the CHSS to enlarge the patient cohort through further enrollment, and to continue the analysis of these late-phase events.

A more recent CHSS multi-institutional study on IAA reported in 2005 by McCrindle and associates¹⁷ evaluated an expanded cohort of 472 patients (including the patients previously reported by Jonas and associates). Additional insights concerning the significance and management of LVOT obstruction became apparent, at least in part because of the large size of the study population. Of the 472 patients with IAA, 143 underwent a variety of interventions to address LVOT obstruction, of which 52 took place some time after the initial IAA repair. Subaortic resection was performed in 75 of these patients, and 51 underwent LVOT bypass procedures (Norwood or Yasui). Two patients required cardiac transplantation. Competing risks analysis revealed that at 16 years after initial admission, 38% were alive without a LVOT procedure,

FIGURE 122-12 ■ Graphic representation from the 2005 Congenital Heart Surgeons' Society study of interrupted aortic arch (IAA) competing risks analysis for subsequent procedure aimed at addressing residual or recurrent left ventricular outflow tract (LVOT) obstruction. All patients began at the time of the initial procedure aimed at addressing potential or actual LVOT obstruction ($N = 143$) and could transition to either death or similar subsequent procedure. *Solid lines*, parametric point estimates; *dashed lines*, limits of 70% confidence intervals; *circles with error bars*, nonparametric estimates; *y-axis*, proportion of patients (expressed as percentage of total) in each of three categories at any given time after IAA repair. (From McCrindle BW, Tchervenkov CI, Konstantinov IE, et al; Congenital Heart Surgeons Society: Risk factors associated with mortality and interventions in 472 neonates with interrupted aortic arch: a Congenital Heart Surgeons Society study. *J Thorac Cardiovasc Surg* 129:343–350, 2005.)

whereas 34% had undergone an initial LVOT procedure (Fig. 122-11). For the 143 patients who had an initial LVOT procedure, there was a high risk of early death and a nearly constant risk of a second procedure. At 16 years after the initial LVOT procedure, 35% were alive without a second procedure, and 28% required a second LVOT procedure. Of the patients who had an initial LVOT procedure, 37% had died by 16 years (Fig. 122-12). Risk factors for a second LVOT procedure were absence of a large VSD and initial balloon dilation of the LVOT. These observations certainly emphasize the significance of the problem of LVOT obstruction in IAA and its negative effects on survival and reoperation-free survival. Regarding the fate of the initial arch repair, reintervention for arch obstruction occurred in 109 cases. Of these, 52 were by transcatheter balloon dilation and 57 were surgical. The time-related hazard function for survival to an arch repair intervention showed two phases: an early phase accounting for 89 events and a smaller constant hazard phase accounting for 20 events. The time-related hazard function for death without an IAA repair intervention was characterized by an early phase only. The competing risks for the two events showed that 16 years after IAA repair, 33% had died without an IAA repair intervention, 29% were surviving to an IAA repair intervention, and 38% remained alive without an IAA repair intervention (Fig. 122-13). Finally, with respect to overall mortality, improving outcomes were evident for patients born later in the study enrollment period (Fig. 122-14). This

FIGURE 122-13 ■ Graphic representation from the 2005 Congenital Heart Surgeons' Society study of interrupted aortic arch (IAA) competing risks analysis for subsequent intervention for residual or recurrent obstruction at IAA repair site. All patients began at the time of repair of IAA ($N = 453$) and could transition to either death or subsequent intervention for residual or recurrent obstruction at the arch repair site. *Solid lines*, parametric point estimates; *dashed lines*, limits of 70% confidence intervals; *circles with error bars*, nonparametric estimates; *y-axis*, proportion of patients (expressed as percentage of total) in each of three categories at any given time after IAA repair. All patients began at the time of initial admission to a CHSS member institution. **A**, Overall survival. **B**, Predicted overall survival for first 5 years after admission, stratified by patient date of birth. *Solid lines*, Parametric point estimates; *dashed lines*, limits of 70% confidence intervals (CI). (From McCrindle BW, Tchervenkov CI, Konstantinov IE, et al; Congenital Heart Surgeons Society: Risk factors associated with mortality and interventions in 472 neonates with interrupted aortic arch: a Congenital Heart Surgeons Society study. *J Thorac Cardiovasc Surg* 129:343–350, 2005.)

positive message regarding steadily improving rates of overall survival over the period of patient enrollment (1987 to 1997) is tempered by the sobering data concerning the significant requirement for late re-interventions. It should also be noted that, while the initial CHSS report was restricted to patients with IAA and VSD, the 2005 report by McCrindle and associates also included patients with complex lesions, including IAA with truncus arteriosus, with an aortopulmonary window, and with a single ventricle.

The most recent report on the CHSS cohort by Jegatheeswaran and associates⁸⁰ clearly reinforced the impression that IAA is a chronic disease, with many repaired patients requiring multiple subsequent procedures. Among 447 patients with IAA enrolled from 1987 to 1997 at 33 institutions, there were 158 subsequent arch interventions and 100 left ventricular outflow tract procedures. Overall freedom from death at 21 years was 60%. The risk of additional subsequent arch procedures decreased after the first subsequent arch procedure in the acute phase, but did not significantly change in the chronic phase. The risk of additional subsequent left ventricular outflow tract procedures increased after the first subsequent left ventricular outflow tract procedure in the chronic phase. These results indicate the need for practitioners, patients, and their families to understand the concept that IAA is a chronic disorder and not a structural anomaly definitively treated in the newborn period.

This concept is further amplified by a recent single-center follow-up study undertaken at the Children's

Hospital of Philadelphia. Intermediate term status of children and adolescents who had undergone repair of IAA as neonates was evaluated by O'Byrne and associates.⁸¹ A cross-sectional study of patients age 8 to 18 years included genetic testing, cardiac magnetic resonance imaging, cardiopulmonary exercise testing, and assessment of health status and health-related quality of life. A concurrent retrospective study reviewed their postoperative use of medical care, including operative and transcatheter reinterventions, noncardiac surgeries, and hospitalizations. Twenty-one subjects with a median age of 9 years were studied. Reintervention rates were 38% for left-ventricular outflow tract, 33% for aortic arch, and 24% for both. Rates of reintervention were highest in the first year of life. Left-ventricular ejection fraction was preserved ($72\% \pm 6\%$). Maximal oxygen consumption, maximal work, and forced vital capacity were significantly decreased from age and sex norms ($P < 0.0001$). Health status and quality of life were both severely decreased.

An uncommon but important complication that can occur after IAA repair is compression of the left mainstem bronchus. This problem has been reported after repair of IAA with VSD and with truncus arteriosus. Signs of this complication may be present or appear early after initial repair; they can cause failure to liberate from mechanical ventilation. While the patient is receiving positive-pressure ventilation, the compression can manifest as air trapping and hyperinflation. Without mechanical support and positive pressure, it can give the opposite picture—that of total atelectasis of the left lung.

Alternatively, it can become evident at some later time after initial repair, with symptoms of wheezing or recurrent respiratory infection. Bronchoscopy reveals extrinsic compression with collapse of the airway. CT or MRI with three-dimensional reconstruction is helpful. The problem occurs when either an interposition graft or a primary anastomosis under tension compresses the left bronchus. Historically, this has been treated with division of the reconstructed aortic arch and placement of an extra-anatomic ascending-to-descending aortic conduit. Mitchell and associates⁸² reported a case of successful management of bronchial compression with severe bronchomalacia in a patient after IAA repair. They achieved transverse aortic arch extension with a pulmonary artery autograft and performed a left bronchial sleeve resection. Advocates of simple primary anastomosis believe that this rare complication can be avoided with full mobilization of all aortic elements at the time of repair. Some believe that dividing an aberrant right subclavian artery at its origin from the descending thoracic aorta contributes to minimization of tension at the anastomosis. Others recommend division of the left subclavian artery at its aortic origin if the anastomosis is under tension. We hold that routine augmentation of the aortic anastomosis with a homograft vascular patch at the time of IAA repair is the best way to minimize tension on the aortic elements and to avoid compression of the adjacent airway, without sacrificing major aortic branches.

Recent emphasis on understanding the neurodevelopmental effects of complex congenital heart disease and its treatment, as well as the influence of underlying genetic abnormalities, has prompted clinical investigators to realize that patients born with aortic arch anomalies are a heterogeneous group for whom risk of neurodevelopmental abnormalities is significant and multifactorial. The Western Canadian Complex Pediatric Therapies Follow-up Group evaluated 26 survivors of neonatal cardiac surgery for IAA at 6 weeks old or younger (1996 and 2006), with multidisciplinary neurodevelopmental assessment at 18 to 24 months of age.⁸³ Mental and psychomotor developmental indices were 75.8 ± 17.1 and 72.3 ± 16.9 , respectively, with significantly lower scores for children with chromosomal abnormalities, which accounted for 29% of the variance in developmental indices. For the remaining 17 children without chromosomal abnormalities, mental and psychomotor developmental indices were 82.7 ± 14.5 and 79.1 ± 14.3 , respectively.

In 2009, investigators in the Netherlands commenced a randomized controlled trial of deep hypothermic circulatory arrest (DHCA) versus antegrade cerebral perfusion (ACP) in neonates undergoing aortic arch reconstruction, with the primary outcome measure being incidence of new postoperative brain injury on MRI. As reported by Algra and associates in 2013,⁸⁴ the protocol included preoperative and 1 week postoperative MRI of the brain. Approximately half of the 36 patients had IAA, and the remainder had other anomalies treated by arch reconstruction with cardiopulmonary bypass in the newborn period. After the thirty-sixth patient, it was clear that there was no difference between DHCA and ACP in terms of new cerebral injury. Preoperatively, 50% of

patients had evidence of cerebral injury. Postoperatively, 14 of 18 (78%) DHCA patients had new injury, versus 13 of 18 (72%) ACP patients ($P = 0.66$). White matter injury was the most common type of injury in both groups, but central infarctions occurred exclusively after ACP (0 vs. 6 of 18; $P = 0.02$). Early motor and cognitive outcome at 24 months was assessed and was similar between groups ($P = 0.28$ and $P = 0.25$, respectively). Additional analysis revealed lower postoperative arterial $p\text{CO}_2$ as a risk factor for new white matter injury. Important conclusions were that perioperative cerebral injury is common in this population and that there was no demonstrable difference in the incidence of perioperative cerebral injury after ACP compared with DHCA. Both techniques resulted in a high incidence of new white matter injury, with central infarctions occurring exclusively following ACP.

SUMMARY

Advancements in surgical technique, and markedly improved survival following initial surgical repair of IAA and associated intracardiac anomalies, have led to the recognition that these patients face ongoing risks associated with residual or recurrent obstructions in both the left ventricular outflow tract and the aortic arch. In addition, many patients face important deficits in exercise performance, health status, and health-related quality of life. In essence, IAA and its associated morbidities should be viewed as a chronic disease. Future improvements in patient management are likely to be based on understanding and acceptance of this challenge.

SUMMARY

Congenital aortic valve disease is one of the more commonly encountered congenital cardiac defects, occurring in 3% to 6% of children born with congenital heart disease. Congenital aortic valve disease primarily manifests as aortic stenosis and tends to be a progressive disease with morbidity and mortality resulting from the hemodynamic burden imposed on the left ventricle. Aortic stenosis is generally defined as a narrowing at the valvar, subvalvar, supravalvar, or multiple levels along the left ventricular outflow tract (LVOT). Although the same pathologic mechanisms are operational in both

congenital and acquired aortic valve disease, the context differs dramatically. Congenital aortic valve pathology often manifests alongside multiple associated cardiovascular lesions, and multiple levels of the LVOT can be involved. There are multiple considerations when caring for these children regarding the timing of intervention and approach (catheter-based intervention versus surgical). Because of growth, behavior, and anticoagulation further surgical considerations often include single versus biventricular repair, valve repair versus replacement, and type of valve replacement. Thus, the evaluation

and treatment of congenital aortic valve disease may present unique anatomic and physiologic considerations. Although aortic insufficiency can afflict congenitally abnormal valves later in life, it is an uncommon lesion during infancy and early childhood. When present in these age groups, it is usually an iatrogenic consequence of a procedure designed to relieve congenital aortic stenosis. This chapter will address these considerations and the related challenges encountered in the surgical treatment of congenital aortic valve disease.

SURGICAL ANATOMY OF THE AORTIC VALVE AND ROOT

The aortic valve and root span the transition from the left ventricular chamber and the systemic circulation, and they include the subaortic LVOT, the aortic valve, and the aortic wall up to the level of the sinotubular junction. Congenital heart disease can involve one or more levels of the aortoventricular complex. A thorough understanding and appreciation of these inconspicuous anatomic relationships form the basis of successful surgical treatment of congenital aortic valve disease, and these relationships will be referred to throughout this chapter.¹

The normal aortic valve sits wedged into the LVOT. In addition to supporting the coronary circulation, this central location places the aortic valve at the nexus of several critical intracardiac structures. Among these structures are the anterior leaflet of the mitral valve, the membranous interventricular septum, and the conduction apparatus. Because multiple levels of the aortoventricular complex can be involved in congenital heart disease, it is helpful to consider the normal anatomy to consist of subvalvular, valvular, and supravvalvular components.

The subvalvular anatomy is dominated by the anatomic relationships among the aortic valve, interventricular septum, membranous septum, mitral valve, and conduction apparatus (Fig. 123-1). Parts of the aortic

leaflets are in fibrous continuity with the anterior leaflet of the mitral valve as well as the tricuspid valve (via the membranous septum). These structures contribute to the central supporting structure of the heart, the fibrous skeleton. In addition to providing points of fixation for the atrioventricular valves, the fibrous skeleton also provides electrical insulation between the atria and the ventricles, restricting impulse conduction to the bundle of His. After arising from the atrioventricular node, the bundle of His penetrates the membranous septum, emerging on the surface of the left ventricular septum immediately below the aortic annulus. Looking through the aortic valve, the bundle will lie beneath the annulus, just below the commissure between the noncoronary and right coronary leaflet. From the surgeon's perspective, important radiations of the bundle reach to the nadir of the right coronary leaflet as they fall away, toward the apex of the heart.

Valvular anatomy is dominated by the semilunar leaflets, commissures, and sinuses of Valsalva. The leaflets and their sinuses are identified by the associated coronary artery. The right coronary artery ostium is found in the right coronary sinus, which is almost directly anterior as viewed by the surgeon. The left coronary artery emerges posteriorly from the left coronary sinus. The leaflets themselves are composed of a fibrous core lined by endothelium. The commissures, along with the free-edge coaptation provided by the leaflets themselves, provide the strength necessary to provide a competent valve.

The aortic sinuses are dilations of the aortic wall above distal to the insertion of the semilunar leaflets, and they are well suited to support the coronary ostia. While the leaflets retract during systole, eddy currents developing within the sinuses prevent occlusion of the coronary ostia by the retracted aortic leaflets. Their presence is probably important to the long-term function of the aortic valve leaflets.²⁻⁴

Finally, the supravvalvular area denotes the transition from the left ventricle–aorta complex to the aorta proper. For practical purposes, this area includes the sinotubular junction, the area just distal to the tips of the commissural posts, and the dilations of the aortic sinuses. Abnormalities at any level can be expected in congenital heart disease, and a discussion of the various forms of congenital aortic valve pathology will be categorized by its level: valvular, subvalvular, or supravvalvular.

FIGURE 123-1 ■ Anatomic relationships within the aortic valve. AV, Atrioventricular.

AORTIC STENOSIS

Valvular Aortic Stenosis

Prevalence

Congenital aortic stenosis has been reported to be present in between 3% and 6% of children with congenital heart disease.⁵ Males are affected more commonly than females with an incidence of 3:1.⁶

Clinical Characteristics

The clinical presentation varies with the severity of the lesion and the age at presentation. In the neonate, critical aortic stenosis may present rapidly and dramatically, with

abrupt hemodynamic deterioration, cardiovascular collapse, and shock. The cardiogram may reveal left ventricular hypertrophy with S-T and T wave abnormalities. On chest radiography, there may be cardiomegaly and pulmonary edema. Transthoracic echocardiogram will rapidly establish the diagnosis, and it is useful to determine the presence of associated abnormalities of the left ventricle, mitral valve, or aortic arch. Aggressive resuscitation with inotropes and prostaglandin is required to support the circulation.

Older children may be asymptomatic, and aortic stenosis may be suggested by physical examination results. Chest pain and exercise intolerance is possible but uncommon. Like the neonate, the diagnosis can be confirmed with echocardiography.

Diagnosis

Physical examination results may be suggestive of the diagnosis of congenital aortic valve disease. There may be a harsh crescendo-decrescendo murmur heard best at the right second interspace, with transmission into the neck. A thrill will be present in the suprasternal notch, and over the right second intercostal spaces in severe aortic stenosis. Because ventricular systole is prolonged in the setting of aortic stenosis, the second heart sound may be prolonged, resulting in narrowly split second heart sound. An associated diastolic murmur would suggest an element of aortic insufficiency.

Electrocardiographic changes are consistent with ventricular hypertrophy, as evidenced by increased left-sided R wave voltage. Changes in S-T segment and T wave in the left precordial leads may denote LV strain. Except in the situation of obvious congestive heart failure, the chest radiograph is usually unremarkable.

Echocardiography. Echocardiography is the mainstay for contemporary diagnosis of congenital aortic valve disease. This noninvasive test provides important anatomic and physiologic information, such as the number and anatomy of the aortic leaflets, the size of the aortic annulus and ascending aorta, the location of the coronary arteries, the adequacy of the subaortic LVOT, and the site of the hemodynamic stenosis. The peak instantaneous gradient can be estimated by measuring the velocity of blood flow across the stenosis, and using a modification of the Bernoulli equation ($\text{velocity [m/sec]}^2 \times 4$).⁷

Recent developments in imaging include the availability of three-dimensional echocardiographic technology. Ventricular mass and volume measurements obtained with three-dimensional echocardiography compare well with those obtained with cardiac magnetic resonance imaging, and their utility in determining the etiology of congenital aortic valvular disease is currently under investigation.⁸

Stress Testing. Stress testing may be helpful in older patients with mild to moderate aortic stenosis in whom symptoms may be vague or suspicious and are not clearly related to the aortic valve disease. Stress-related changes in the S-T segment or T wave morphology would suggest important stenosis with myocardium at jeopardy. In these

instances, relief of the stenosis should be seriously considered, despite mild to moderate resting peak gradients.

Cardiac Catheterization. Currently, the major roles of cardiac catheterization include diagnostic and therapeutic options. Diagnostically, catheterization may be helpful to assess left ventricular diastolic function, pulmonary artery pressure, and associated vascular lesions. Therapeutically, balloon valvotomy can be used in patients with isolated aortic valvular stenosis or occasionally in patients with complex multilevel LVOT obstruction.

Natural History

Critical "valvular" aortic stenosis in the neonate often presents as an "emergent" situation, and without prompt treatment these children may succumb from cardiovascular collapse. By contrast, older children with aortic stenosis are often asymptomatic. Given the important considerations pertaining to pediatric aortic valve repair and replacement, the timing of the operation becomes an important consideration, and understanding the natural history and progression of asymptomatic children is useful.

Aortic valve disease in children tends to be a progressive disease. Valvar aortic stenosis can be classified as mild, moderate, or severe. Categorized by Hossack and colleagues,⁹ mild stenosis includes those patients with normal pulse volumes with a resting peak systolic gradient (measured at catheterization) between the left ventricle and aorta of less than 40 mm Hg. Patients are considered to have moderate aortic stenosis when they exhibit diminished pulse volumes by palpation and resting peak systolic gradients of 40 to 75 mm Hg at rest. Patients are considered to have severe stenosis when they present with abnormal pulse volumes and a resting peak systolic pressure gradient in excess of 75 mm Hg.

It should be noted that these gradient criteria were obtained at catheterization by direct pullback measurements. Currently, gradients across the LVOT are frequently obtained with echocardiography, and in most cases Doppler-derived peak instantaneous gradient correlates well with catheter-derived data; however, at lower gradients, Doppler echocardiography can result in an overestimation.^{10,11}

Because aortic valve disease in children is a progressive disease, the natural history of this progression is of some interest. Among children with nonobstructive aortic lesions, Mills and colleagues¹² reported that 7% progressed to mild obstruction after 7 to 15 years. When mild stenosis was present upon the initial evaluation, progression was rapid.¹² Twenty percent of patients developed moderate or severe stenosis within 10 years, with 45% progressing within 20 years. Finally, approximately 60% of patients presenting with moderate stenosis will progress to severe stenosis within 10 years.⁹

Treatment

Catheter versus Surgical Relief of Aortic Stenosis in the Neonate. Aortic stenosis presenting in the neonatal

FIGURE 123-2 ■ Pathologic specimen showing aortic stenosis in the neonatal heart.

period can be a severe hemodynamic lesion that is life threatening (Fig. 123-2). These children often present in shock as a consequence of ductal closure in the setting of left heart structures that are inadequate to support the systemic circulation; their systemic circulation is “ductal dependent.” These children require urgent medical stabilization, including assisted ventilation and inotropic support. Prostaglandin E1 is administered to reopen the duct and to maintain ductal patency. Once stabilized, a thorough echocardiographic examination of the left-sided structures is required to determine their suitability to support the systemic circulation.

When approaching critical aortic stenosis in neonates, the single most important decision regarding treatment is to decide which patients will benefit from biventricular repair, and which are better suited to a single ventricle approach. The importance of proper treatment selection is reflected by the high mortality in older, unstratified series of neonates undergoing valvotomy for critical aortic stenosis.¹³ An accurate determination of which patients will benefit from a single ventricle treatment pathway (Stage I/Norwood operation) is critical, and it has been the impetus for the study sponsored by the Congenital Heart Surgeons Society (CHSS) and designed to accomplish this.¹⁴ An estimate of survival benefit for specific left heart morphology can be obtained at the CHSS website (www.chssdc.org). The management of these patients has been detailed elsewhere. This discussion will focus on patients with aortic stenosis as the dominant lesion in the setting of two adequate ventricles.

For patients with anatomy deemed suitable to support a two-ventricle circulation, aortic valvotomy provides

effective relief of aortic stenosis. Two techniques of aortic valvotomy have been developed: balloon dilation of the stenotic valve and surgical valvotomy (open and closed). While balloon valvotomy is the favored technique at many institutions, surgical valvotomy remains preferred by some. Proponents of balloon valvotomy cite avoidance of potential surgical morbidity, while advocates of surgical valvotomy maintain that a more accurate valvotomy is possible under direct vision.

Although there are no prospective randomized studies directly comparing these two techniques, some data are available. McCrindle and colleagues¹⁵ reported a CHSS-sponsored multi-institutional review of 110 neonates undergoing either surgical (28) or balloon (82) valvotomy for critical aortic valve stenosis in the neonatal period. Survival was similar between the two procedures (82% at 1 month, 72% at 5 years).¹⁵ Balloon valvotomy was more effective at relieving stenosis (mean residual gradient 20 vs. 36 mm Hg), but it was accomplished at the expense of a higher incidence of important aortic insufficiency (18% after balloon valvotomy versus 3% after surgical valvotomy). Despite these differences, the outcome data between the two techniques is comparable. Overall freedom from reintervention was similar for both groups (91% at 1 month, 48% at 5 years). The need for subsequent procedures, regardless of technique, emphasizes the palliative nature of valvotomy for critical aortic stenosis.

McElhinney and colleagues¹⁶ reported medium- and long-term follow-up of 113 patients (age ≤ 60 days) from Children’s Hospital Boston performed between 1985 and 2002. They reported a normalization of aortic annular and left ventricular end-diastolic dimensions within 1 to 2 years. Freedom from moderate or severe aortic regurgitation was 65%, with a reintervention free survival of 48% at 5 years. These data suggest that early relief of the LVOT obstruction allows for catch-up growth without neonatal surgery.

Although balloon valvotomy has assumed a prominent role in the treatment of congenital aortic stenosis in many institutions, its role vis-à-vis surgical valvotomy remains controversial. Hawkins and colleagues¹⁷ have estimated the incidence of aortic valve operation after balloon valvotomy to be 5% to 7% per year. Others have reported the risk of surgery to be lower, but the incidence of reintervention, including subsequent balloon dilation, remains high (60% at 8 years).¹⁸ It may be, however, that specific aortic valvular substrates lend themselves to one treatment or the other. In a group of 54 infants (57% neonates) undergoing surgical aortic valvotomy, Bhabra and colleagues¹⁹ reported significant differences in the long-term outcomes based on leaflet morphology. When valvotomy resulted in a trileaflet structure, patients did significantly better than when only a bileaflet valve was achieved. At 10 years, the actuarial freedom from reintervention was 92% among trileaflet valves, but only 33% among bileaflet valves ($P = 0.01$). Similar differences were reported for freedom from aortic valve reoperation ($P = 0.04$). Freedom from aortic valve replacement (AVR) was 100% in trileaflet valves and 57% in bileaflet valves. However, by echocardiogram, the authors were only able to retrospectively identify 14 of 28 bileaflet valves,

whereas 7 of 8 valves with trileaflet potential could be identified (88% sensitivity, 50% specificity). These results have yet to be confirmed, but closer examination of the anatomic subtypes of aortic valve stenosis may be justified before selecting the appropriate technique.

Currently there appears to be little if any role for surgical transventricular (closed) aortic valvotomy.

Catheter versus Surgical Relief of Aortic Stenosis in Infancy. A few studies have compared balloon aortic valvotomy to surgical valvotomy in older children. McCrindle and colleagues²⁰ reported their analysis of 630 balloon valvotomies on 606 patients from 23 institutions, with a median age of 6.8 years (range, 1 day to 18 years). The procedure was abandoned 4.1% of the time because of technical issues, and procedural mortality was 1.9%. A suboptimal result (including failure to complete procedure, residual gradient >60 mm Hg, left ventricle aortic pressure ≥ 1.6) or major morbidity or mortality were reported in 17% of patients. Independent risk factors for poor outcomes were age less than 3 months, earlier procedure date, higher preoperative gradient, unrepaired aortic coarctation, and the use of undersized balloons.

Other groups have reported similar results with balloon valvotomy in non-neonates. Moore and colleagues reported successful dilation in 87% of patients (129/148), with a very low procedural mortality (0.7%) and good long-term survival (95% at 8 years).¹⁸ Freedom from reintervention at 8 years was 50%, a figure that is consistent with other studies.²¹

In these patients, the risk of repeated intervention was related to the degree of regurgitation and to residual gradients after initial balloon valvotomy. Reminiscent of the report by Bhabra and colleagues,¹⁹ they reported differential results based on angiographic morphology of the stenotic aortic valve; however, as in neonates, it is difficult to demonstrate clearly the superiority of balloon or surgical aortic valvotomy. Chartrand and colleagues²² reported their experience with 67 children (age > 6 months) undergoing surgical valvotomy during 1960 to 1992. There was no operative mortality, and the 20-year freedom from death, reoperation, and AVR was 94%, 63%, and 73%, respectively. The authors concluded that surgical valvuloplasty is a safe and effective procedure with durable results.

In summary, as in neonates, aortic valve morphology appears to influence the response to intervention in infants, and further characterization may be justified. Currently there appear to be institutional preferences for balloon or surgical valvotomy that can be defended on the basis of experience.

Aortic Stenosis in the Older Child. In contrast to clinical presentation of the neonate with critical aortic stenosis, older children are commonly asymptomatic. For them, durable preservation of left ventricular function becomes the primary goal of treatment. The etiology of aortic stenosis in the older child (>1 year of age) is most commonly due to valvular aortic stenosis (79%), followed by subvalvular aortic stenosis (7%) and supra-aortic stenosis (6%) being much less common.⁶ Aortic regurgitation is often associated with congenital aortic stenosis and

may be the result of previous interventions for the relief of stenosis.

Older children with aortic stenosis generally enjoy normal growth and development. When present, symptoms such as chest pain, exercise intolerance, or syncope constitute clear surgical indications. For asymptomatic patients, the indications for intervention are subtler. For patients with severe stenosis in whom the left ventricle to aortic (LV-Ao) gradient is greater than 75 mm Hg, operation is recommended. For children thought to have moderate stenosis (40-75 mm Hg LV-Ao gradient), more information may be needed before a recommendation can be made. In this setting, electrocardiographic changes (ST-T wave changes consistent with left ventricular strain, left ventricular hypertrophy) or a positive stress test result would be indications for operation. For these asymptomatic patients, somatic growth, surgical options, and timing of intervention become important concerns.

Because of the progressive nature of the disease, older children thought to have mild aortic stenosis (gradient < 40 mm Hg) should be followed with periodic examinations and echocardiograms. It should be remembered that the gradient depends on the cardiac output and in a severely dysfunctional left ventricle the gradient may be unimpressive.

The management options for older children depend on the context of their disease. Older children newly diagnosed with important aortic stenosis with minimal insufficiency may be well served by balloon valvotomy. The more common scenario is several years of excellent palliation following an initial valvotomy, during which time the child grows and develops normally. However, with time or repeated interventions, or both, many patients will develop important aortic insufficiency (see Aortic Regurgitation section). Any residual valvular stenosis can be magnified by the resulting volume load, and the combinations of these lesions conspire to threaten left ventricular function. However, by virtue of their older age and larger size, these children are better candidates for durable surgical palliation, usually including valve replacement.

SUBVALVULAR AORTIC STENOSIS

Congenital subvalvular aortic stenosis is an obstruction below the aortic valve secondary to a discrete or short, localized fibrous or fibromuscular ridge or a longer diffuse fibromuscular tunnel (Fig. 123-3). It is important to note that there is a spectrum between discrete and tunnel-like subaortic stenosis, which has contributed the variable difference in the reported prevalence. In addition, it is often difficult to distinguish hypertrophic obstructive cardiomyopathy from tunnel-like subaortic stenosis (see [Hypertrophic Obstructive Cardiomyopathy](#)).

Subaortic Membrane

Subaortic membrane is found in association with other congenital lesions in 60% to 70% of cases, with ventral septal defect being the most common (35%).²³

FIGURE 123-3 ■ Examples of forms of (A) fixed aortic stenosis, (B) discrete membrane, (C) tunnel-like stenosis, and (D) muscular obstruction.

Membranous subaortic stenosis results from the proliferation of fibrous tissue just beneath the leaflets of the aortic valve. This tissue may be very thin and tough, and is often circumferential, involving the underside of the anterior leaflet of the mitral valve. In fact, careful review of the echocardiogram may suggest a hinge point representing tethering on the leaflet by the membrane.^{24,25} Although the etiology of this form of aortic pathology is not known, studies have implicated shear stress, precipitated by abnormal angles between the ventricular septum and the aortic barrel, as playing an important role. The addition of a ventral septal defect adds to the generation of shear stress in this setting.²⁶

Natural History and Surgical Indications

In general, the surgical indications for membranous subaortic stenosis adhere to the general recommendations for aortic stenosis. However, citing a lower incidence of recurrence, some centers advocate earlier surgical resection for subaortic stenosis. Brauner and colleagues²⁷ reported that the recurrence rate of subaortic stenosis (predominately composed of membranous, but with a few tunnel-like stenoses) was related to a preoperative gradient of 40 mm Hg or greater and suggested that surgical resection at lower gradients was justified. Others have advocated repair at the time of diagnosis, irrespective of the gradient.^{28,29} However, the advantages

of early intervention have not been confirmed, as other investigators have reported no benefit of early surgery on recurrence.³⁰

Because the timing of surgery remains controversial, it is helpful to examine the natural history of membranous subaortic stenosis. There are data suggesting that some children with mild subaortic stenosis (peak systolic gradient < 40 mm Hg) might not require surgery for several years. A large representative study of the rate of progression of subvalvular aortic stenosis was reported by Rohlicek and colleagues³¹ studying children from several centers in Eastern Canada. To document the natural history and surgical outcomes, they followed 92 children from the time of diagnosis. There were slightly more males (1.6:1), and the mean age at diagnosis was 5.3 years. Thirteen patients had bicuspid aortic valves. At a mean follow-up of four years, 42 of these children ultimately came to surgery an average of 2.2 ± 0.4 years after diagnosis; 44 were followed medically and never came to operation. Children ultimately requiring surgery presented with higher initial gradients (40 ± 5 mm Hg vs. 21 ± 2 mm Hg) and were more likely to present with aortic insufficiency at diagnosis (35% vs. 13%). Analysis showed the echo gradient at diagnosis to be predictive of subsequent gradient progression as well as the appearance of aortic insufficiency. Eight children undergoing surgery required reoperation for recurrent subaortic stenosis at an average of 4.9 ± 0.9 years after initial resection. These patients initially presented with significantly higher gradients (66 ± 10 mm Hg).

In contrast to a more aggressive approach of aggressive surgical resection of membranous subaortic stenosis at time of diagnosis, these data suggest that a significant proportion of these patients will have stable or at least slowly progressive gradients. The management approach to patients remains variable, but it seems reasonable to pursue surgical resection for peak systolic gradients of 40 mm Hg or greater (obtained by echocardiography). The new onset of aortic insufficiency should be considered an important indication for surgery, regardless of the gradient. While these authors did not discern any improvement in aortic insufficiency following operation, it has been the experience of others that careful débridement of fibrous tissue encroaching on the aortic leaflets often results in significant improvement in aortic insufficiency.³²

Surgical Approach

The surgical approach to this lesion requires cardiopulmonary bypass. A single right atrial venous cannula is usually adequate. The aortic valve is exposed through a transverse aortotomy, which can be carried down into the noncoronary sinus if needed. Careful retraction of the aortic leaflets will reveal the subaortic membrane. The distance between the aortic valve and the membrane may vary slightly, but can usually be well visualized. The membrane is incised in the safe zone of the ventricular septum, just leftward of the nadir of the right coronary sinus. In many instances, the membrane can be peeled or endarterectomized from the endocardium anteriorly and rightward, and from the anterior leaflet of the mitral

valve posteriorly. In severe cases, this membrane may encroach upon and even involve the belly of the aortic valve leaflets. In this instance, the leaflets require careful débridement of the thick, fibrous tissue.

Surgical Results

Membranous subaortic stenosis has been the subject of intense scrutiny for its incidence and its propensity for recurrence after seemingly adequate surgical resection. The recurrence rate for membranous subaortic stenosis has been reported to be between 0% and 55%, with most reports documenting a recurrence rate of 15% to 21%.^{30,33-37}

Independent predictors of reoperation for recurrent subaortic stenosis include proximity of the membrane to the aortic valve (<6 mm), and a peak gradient greater than 60 mm Hg. Adherence of the membrane to the aortic or mitral valve identified at surgery was also a predictor for recurrence.³⁸ Septal myotomy, in addition to membrane resection, has been reported to reduce the incidence of recurrence. Lupinetti and colleagues³⁹ reported a recurrence rate of 4% when a septal myotomy was performed in addition to membrane resection; however, this finding has not been confirmed by others.^{27,40}

Other surgeons advocate an even more aggressive approach. Yacoub and colleagues³³ have suggested that an important pathologic feature of membranous subaortic stenosis is fibrous tissue ingrowth at the point of insertion of the anterior leaflet of the mitral valve into the left ventricular myocardium (Fig. 123-4). This ingrowth interferes with dynamic widening of the outflow tract, including posterior displacement of the mitral apparatus, during systole. Adding resection of the fibrous tissue from the mitral valve trigones to membrane resection and septal myotomy, Yacoub and colleagues³³ reported excellent relief of LVOT gradient (mean, 8 mm Hg) in 57 patients. Over an average follow-up of 15 years, seven patients had mild to moderate aortic regurgitation, but importantly, no patient required reoperation for recurrent stenosis.

FIGURE 123-4 ■ Pathologic specimen showing fibrous tissue ingrowth at the insertion of the anterior leaflet of the mitral valve into the left ventricle.

While periodic attempts at balloon dilation in these patients have been performed, the resulting gradients are generally high (≈ 30 mm Hg), and subsequent surgery is required in a majority. Among 13 patients undergoing dilation, Moskowitz and colleagues⁴¹ reported that 9 required subsequent surgery. Suarez de Lezo and colleagues^{42,43} reported a 50% recurrence rate within 3 years. At this time, balloon dilation should not be considered a primary treatment of discrete subaortic stenosis.

Tunnel-Like Subaortic Stenosis

Long segment or tunnel-like stenosis has been defined as a muscular or fibromuscular subaortic stenosis, the length of which was more than one third the aortic diameter.⁴⁴ While tunnel-like stenosis may be associated with other lesions, such as interrupted aortic arch and atrioventricular septal defect, this discussion will confine itself to diffuse, long segment, or tunnel-like stenosis in the setting of concordant atrioventricular and ventriculoarterial connections with an intact ventricular septum. The indications for operation for subaortic tunnel are similar to those described for membranous subaortic obstruction.

Surgical Treatment Options

Modified Konno Operation

Surgical Indications. The indications for the modified Konno operation in the relief of subaortic obstruction are evolving. Roughneen and others described their experience with the modified Konno operation in 16 children.^{45,46} Indications for operation were recurrent subaortic stenosis (3), hypertrophic subaortic stenosis (3), tunnel stenosis of the LVOT (2), and subaortic stenosis following atrioventricular septal defect (2), or ventricular septal defect (VSD) (5). Long-term follow-up will be important for these patients, as it is likely a large number of these patients will have recurrent sub AS.

Surgical Approach. The degree of hypoplasia encountered in tunnel-like subaortic stenosis does not lend itself to transaortic resection, as might be performed for membranous subaortic stenosis. The surgical treatment of tunnel-like stenosis requires a more extensive procedure. In the presence of a suitable aortic valve, the modified Konno operation has become a favored option when approaching tunnel-like subaortic stenosis. It has the great appeal of enlarging the LVOT while preserving the native aortic valve. Excellent technical reviews of this technique are available.^{45,47,48}

Briefly, under moderate hypothermia with bicaval cannulation, an aortotomy is performed, and the aortic valve and subaortic area is examined. Only if the aortic valve is satisfactory should the valve-sparing modified Konno operation be performed. If the valve is inadequate, a more extensive procedure designed to enlarge the LVOT and replace the aortic valve will be necessary, such as the Konno-Rastan (discussed later) or Ross-Konno operation.

After inspection of the aortic valve, the infundibulum of the right ventricle is incised in a transverse fashion. Visualization of the ventricular septum from these two

perspectives (through the aortic valve and through the infundibulum) allows an accurate incision through the ventricular septum (Fig. 123-5). Indentation of the safe area of ventricular septum (leftward of the nadir of the right coronary leaflet) with a right-angled clamp placed through the aortic valve allows an accurate incision through the septum via the infundibulotomy. Alternatively, a stitch can be placed from the LVOT to the right ventricular outflow tract (RVOT) to pull up and help guide this incision. It is important that the trajectory of this incision be directed toward the apex of the left ventricle, which from the surgeon's perspective is almost directly leftward, and carried as distally as necessary to relieve the obstruction. Proximally the incision can be carried up to, and if necessary into, the commissure between the right and left aortic leaflets. Septal tissue can be débrided from the left ventricle side of the septum, but this should be on the leftward portion of the incision, to spare the left-sided conduction apparatus as it courses down the ventricular septum. The resulting VSD is then closed with a generous patch (Dacron or polytetrafluoroethylene) augmenting the LVOT. The aortic valve is carefully débrided of any fibrous tissue, and the incision is closed.

Surgical Results. The modified Konno operation is highly effective in reducing the LVOT gradient, and it can be achieved without damage to the conduction tissue.

In the series by Jahangiri and colleagues,⁴⁵ 15 of 46 patients with tunnel-like sub AS underwent a modified Konno procedure with excellent relief of LVOT obstruction and minimal incidence of aortic regurgitation and heart block.⁴⁵ Caldarone and colleagues⁴⁹ reported similar results among 18 patients. Although the technique is highly effective in relieving subaortic stenosis resulting from a variety of lesions, complications can occur. In general, operative mortality among published reports has been negligible. However, right bundle branch block has been commonly noted following the modified Konno operation. This is significant in the setting of preexisting left bundle branch blocks, as may exist following trans-aortic resection of subaortic stenosis, and complete heart block has been noted in up to 12.5% of cases. Although the aortic valve is at risk and residual VSDs can occur, these complications are uncommon with careful technique. Given these results, some surgeons have advocated this operation for recurrent membranous subaortic stenosis. While the modified Konno certainly alters the geometry of the LVOT, thought to contribute to the genesis of membrane, its effect on additional recurrences is unknown.

Konno-Rastan Aortoventriculoplasty

Surgical Approach. The Konno-Rastan operation, described independently by Konno and Rastan in 1975

FIGURE 123-5 ■ Modified Konno operation. **A**, Transverse incision of the infundibulum showing the perspective of the ventricle septum through the aortic valve and the infundibulum. **B**, Superimposed patches of the ventricular septum and the infundibulum, respectively.

FIGURE 123-6 ■ Konno-Rastan aortoventriculoplasty. **A**, Atrioventriculoplasty with valve insertion. **B**, Closure of ventricular septal defect; aorta with Dacron patch. **C**, Closure of right ventricular outflow tract.

and 1976,^{50,51} is required when tunnel-like subaortic stenosis coexists with significant aortic valve pathology. Incision of the ventricular septum, as performed in the modified Konno operation through the aortic annulus, and the ascending aorta, provides effective relief of all levels of obstruction. This operation requires bicaval cannulation. A vertical aortotomy is made leftward of the right coronary artery. At this point, an incision in the infundibulum of the right ventricle is helpful in guiding the septal incision. The annulus of the aortic valve is incised leftward of the nadir of the right coronary leaflet, and extended into the interventricular septum, relieving the subaortic stenosis. The aortic annulus is débrided, and an appropriately sized mechanical (or biological) prosthesis is inserted and fixed into the posterior annulus. A patch of Dacron or polytetrafluoroethylene is fashioned such that it enlarges the LVOT, and it is sutured into place up to the aortic annulus enlarging the subaortic dimensions. Sutures are then passed through the valve sewing ring and patch, reestablishing annular continuity. The patch is then carried distally, enlarging and closing the ascending aorta (Fig. 123-6). The enlargement or width of the Dacron patch has to be considered carefully because the right coronary artery anatomy can be altered. Figure 123-7 is an example of a distorted right coronary artery following aortic root enlargement. If the aortic root is extremely hypoplastic, a Nicks-type incision in the contralateral sinus may allow a more uniform aortic root enlargement. The RVOT is repaired, allowing adequate

FIGURE 123-7 ■ Cardiac catheterization showing a distorted right coronary artery after Konno-Rastan aortoventriculoplasty.

clearance for the underlying augmented LVOT. Treated bovine pericardium works well for this application.

Surgical Results. The results of the Konno operation have improved since its introduction in 1975. Erez and colleagues⁵² reported their experience with the Konno operation in 60 pediatric patients between 1982 and 2000. Forty-two received mechanical valves, nine received homografts, six received xenografts, and fifteen received

FIGURE 123-8 ■ Overall survival rate. The actuarial survival rates calculated with the Kaplan-Meier curves were 91.9% at 10 years and 87.7% at 15 years. (From Sakamoto T, Matsumura G, Kosaka Y, et al: Long-term results of Konno procedure for complex left ventricular outflow tract obstruction. *Eur J Cardiothorac Surg* 34:37–41, 2008.)

FIGURE 123-9 ■ Freedom from all events. Event-free rates including all mortality, reoperation, catheter intervention, and significant complications were 75.2% at 10 years and 67.2% at 15 years. (From Sakamoto T, Matsumura G, Kosaka Y, et al: Long-term results of Konno procedure for complex left ventricular outflow tract obstruction. *Eur J Cardiothorac Surg* 34:37–41, 2008.)

autografts. Operative mortality declined from 25% early in the experience to approximately 10%, which is comparable to other contemporary pediatric series.^{53–55} Similar recent results were reported in 63 patients by Sakamoto and colleagues⁵⁶ undergoing the Konno operation using a mechanical valve (Figs. 123-8 and 123-9). Although mortality has continued to decline, complications remain common. Sixteen percent of patients with a Konno operation or prosthetic valve required surgical reexploration for bleeding, whereas only 6.8% (1 of 15) of patients undergoing Ross-Konno operation required reoperation for bleeding. Heart block occurred in 8.8% of Konno or prosthetic valve operations and in 6.7% of Ross-Konno operations. Long-term survival for the Konno operation has been related to the underlying pathology and recurrent or residual LVOT obstruction that might require complex reoperations.

The freedom from reoperation following the Konno operation has not been satisfactory. Among patients

FIGURE 123-10 ■ Comparison of failure rate percentage of Ross, mechanical, and biological procedures and time to reoperation.

receiving biologic valves (homograft or xenografts), freedom from reoperation at 10 years was 0% (Fig. 123-10). Reoperation was primarily for valve failure. The patients with mechanical valves primarily required reoperation for valve outgrowth (6) and endocarditis (3).

Ross-Konno Operation. There is limited long-term follow-up on patients undergoing neonatal or infant Ross-Konno operation. Among the 15 patients undergoing the Ross-Konno operation between 1997 and 2000, there was one operative death (6.7%) and two late deaths in syndromic children. While the authors concluded that the Ross-Konno operation was less morbid, the durability of the autograft in the aortic position remains a concern, especially in the very young.⁴⁹ Ohye and colleagues⁵⁷ have reported their neonatal and infant experience in 10 patients with the Ross-Konno operation. At a median follow-up of 48 months, they reported no reoperations on the autograft, although two patients have developed significant autograft insufficiency, and there was no operative mortality. More recently, Brown and colleagues⁵⁸ reported their experience in 14 patients with a mean follow-up of 5.7 years and an actuarial survival at 10 years of 86%. Freedom from RVOT and autograft reoperation at 10 years was 77% and 92%, respectively. Oka and colleagues⁵⁹ reported their experience in patients undergoing Ross-Konno and associated mitral valve procedures. Patients undergoing concomitant mitral valve operation had significantly more morbidity and mortality; actuarial survival at 5 years was 44% versus 92%.⁵⁹ Despite concerns about the durability of the autograft, the Ross-Konno probably presents the best available option for relief of complex LVOT obstruction in small children (Fig. 123-11).

Aortoapical Conduit. The aortoapical conduit is largely of historic interest. Brown and colleagues reported their experience in 22 children with tunnel-like stenosis between 1978 and 1992.³⁴ They reported one early death and six late deaths, for an overall mortality of 32%. The ACC is associated with a high rate of reoperation and poor long-term durability.⁶⁰ This technique has largely been abandoned in favor of surgical alternatives, such as

FIGURE 123-11 ■ Ross-Konno operation for complex left ventricular outflow tract obstruction in a small child. AAn, Aortic annulus; Ao, aorta; IVS, interventricular septum; PA, pulmonary artery.

the modified Konno, Konno-Rastan, and Ross-Konno procedures.

Hypertrophic Obstructive Cardiomyopathy

Hypertrophic obstructive cardiomyopathy (HOCM) is an autosomal dominant disease with limited information on children.⁶¹ Some of these patients develop a dynamic form of subaortic LVOT obstruction that results from myocardial hypertrophy prominently affecting the interventricular septum, but also can affect the mid-ventricle and LV apex. A variety of treatments, including calcium channel blockers, beta blockers, and dual-chamber pacing have met with mixed success.⁶²⁻⁶⁵

Surgical relief can be accomplished by transaortic septal myotomy designed to relieve the subaortic septal muscular obstruction. First described by Morrow and colleagues,⁶⁶ septal myotomy provides effective hemodynamic relief of the obstruction and can be expected to

provide both symptomatic relief and improvement in New York Heart Association class. Improvement in survival, however, has been more difficult to document. Despite an operative mortality of 1% to 2%, the subsequent annual mortality rate approaches 2%, comparable to that reported in patients treated nonsurgically.⁶⁷ Recently, the modified Konno operation has also been applied successfully to HOCM.

Surgical Indications

Surgical indications for this condition remain controversial.⁶⁸ In general, operation has been advocated for symptomatic patients (New York Heart Association class III-IV) with peak instantaneous gradients exceeding 50 mm Hg, or asymptomatic patients with gradients exceeding 100 mm Hg, despite medical management.^{69,70}

More recently, attenuation of the interventricular septum has been induced by the injection of absolute ethanol into the proximal septal coronary artery.⁷¹ This technique has been successful in lowering the outflow tract gradient by 60% to 80%, but 11% to 29% of these patients develop complete heart block.^{72,73} Although alcohol ablation holds promise, it represents a selective alternative to surgical therapy, and currently it has no place in the treatment of young children. Currently, septal myomectomy remains the gold standard for medically refractory symptomatic patients with high-grade LVOT obstruction.⁷⁴

Preoperative Assessment

In the preoperative assessment, it is important to establish the extent of the hypertrophy and the mechanism of any associated mitral regurgitation (MR). Most patients with HOCM have some MR, and it is generally related to systolic anterior motion (SAM) of the mitral valve. The typical posteriorly directed MR that occurs after the SAM of the mitral valve is generally alleviated with septal myectomy alone; however, if the MR precedes the SAM, the MR will likely persist after myectomy. Caution is warranted if placing a ring annuloplasty, because it increases the risk of SAM. In older patients, one must rule out coronary disease or any associated myocardial bridges.⁷⁵

Surgical Approach

Standard cardiopulmonary bypass with mild hypothermia is initiated. Because of the extreme hypertrophy, myocardial protection is critically important. Topical cooling and cold blood cardioplegia are used. Once the heart is arrested, vented, and cooled, an oblique hockey-stick incision is used to expose the aortic root. Looking into the subaortic area, the papillary muscles and chordae are obscured by the septum. An index finger in the LVOT and a thumb anterior to the RVOT confirms the septal thickness. The landmarks for the myectomy incisions are the area immediately below the middle of the right coronary cusp and the leftward muscle bar that extends to the mitral valve. The left bundle branch of the conduction system is under the commissure between the right and noncoronary cusp, and it extends leftward. After

resection, the Doppler gradient should remain less than 15 to 20 mm Hg. On occasion there will be inconsequential fistulous connections from the divided septal coronary arteries.^{76,77}

Surgical Results

Ommen and colleagues⁷⁸ reported a multi-institutional experience analyzing the effect of surgical myectomy on long-term survival in hypertrophic cardiomyopathy. Operative mortality was 0.8%, and 1-, 5-, and 10-year overall survival was 98%, 96%, and 83%, respectively. When comparing operated with nonoperated HOCM, operated myectomy patients experienced significantly improved survival ($P < 0.001$).⁷⁸ More recently, Swistel and colleagues⁷⁹ reported on 16 patients with complete follow-up at 2.5 years and no deaths, reoperations, or other adverse consequences. The mean preoperative, postoperative, and late LVOT gradients were 137 ± 45 , 10 ± 17 , and 6 ± 14 mm Hg.⁷⁹ Altarabsheh and colleagues⁸⁰ reported a large series of 127 children (12.9 ± 5.9 years) who underwent septal myectomy for HOCM. Preoperative mean gradient was 89 mm Hg and 95% had MR related to SAM. Mean follow-up was 8.3 years; there were no early deaths and four late deaths. Overall survival was 91%, 88%, 79%, and 73% at 1-, 5-, 10-, 15-, and 20 years, respectively. Six patients underwent repeated septal myectomy. The authors' data support improved late survival with myectomy compared with previous reports in patients with untreated HOCM.⁸⁰

Supravalvular Stenosis

Supravalvular aortic stenosis (SVAS) is the least common form of aortic stenosis, accounting for 6% to 7% of aortic outflow abnormalities. First described by Mencarelli in 1930,⁸¹ supravalvular aortic stenosis is the result of narrowing of the aorta beginning just above the aortic valve, usually at the level of the sinotubular junction. The gender incidence is more equitable than most forms of aortic stenosis with an approximately 1:1 male-to-female ratio. In 1961, Williams and colleagues⁸² described the common association of several other features, including characteristic facial features (elfin facies), mental retardation, and, infrequently, hypercalcemia.⁸² Soon afterwards, an association with Williams syndrome and peripheral pulmonary artery stenosis was identified.^{83,84}

In addition to its association with Williams syndrome, SVAS occurs in a familial form transmitted by autosomal dominant inheritance, and in a sporadic form. Microdeletion of chromosome 7q11.23 has been identified in patients suffering from all three forms of supravalvular stenosis.^{44,85} Affected individuals express only about 50% of the normal amount of tropoelastin, resulting in reduced elastin deposition and fiber disorganization within the arterial wall.

Clinical Presentation

Williams syndrome may be suggested on the basis of characteristic facies, and all patients with possible Williams syndrome should be evaluated for supravalvular aortic stenosis. Any asymptomatic patient with a familial

FIGURE 123-12 ■ Extent of supravalvular aortic stenosis determined by catheterization.

history should be evaluated, and the presence of a cardiac murmur or thrill should undergo echocardiography.

Other, nonaortic vascular lesions are commonly present and should be sought. These lesions include pulmonary artery stenosis (30%), renal artery stenosis (5%), and coarctation of the aorta (15%).⁸⁶ The degree of involvement in the aorta can vary from localized disease at the sinotubular junction with or without left main coronary ostial involvement, to diffuse involvement of the aortic arch and brachiocephalic vessels. Thus, patients with supravalvular aortic stenosis should undergo catheterization to fully delineate the extent of vascular involvement (Fig. 123-12).

Surgical Indications

Like the other forms of aortic obstruction, supravalvular aortic stenosis tends to be a progressive lesion. Indications for operation are generally consistent with those in other forms of aortic stenosis (symptoms, gradient >40 –50 mm Hg). Syncope or chest pain may represent cuspal adherence to the sinotubular junction and episodic coronary ischemia, and it is a clear indication for surgery.⁸⁷

Significant pulmonary artery stenosis is often present in patients requiring relief of supravalvular aortic stenosis. Surgery should not be delayed in these patients, as the natural history of associated pulmonary stenosis is generally indolent, with regression of these lesions over time. However, a few patients will have severe central or branch pulmonary artery stenosis, or both, and in the presence of markedly elevated right ventricular pressures, relief of the pulmonary artery stenosis should also be performed if the lesions are surgically accessible.

Surgical Approach

The surgical treatment of SVAS is determined by the extent of the stenosis. A variety of techniques have been used to relieve localized SVAS. In 1961 at the Mayo

FIGURE 123-13 ■ Surgical treatment of supravulvar aortic stenosis. **A**, Single-patch technique into noncoronary sinus. **B**, Two-sinus augmentation technique (Doty). **C**, Three-patch (modified Brom). **D**, Autologous interdigitating technique. **E**, Cranial view of aortic sinus incisions. *LCA*, Left coronary artery; *RCA*, right coronary artery.

clinic, McGoon and colleagues⁸⁸ initially described a single-patch technique, with the placement of a teardrop or diamond-shaped patch across the sinotubular junction, extending between the bases of the noncoronary sinus into the ascending aorta. Doty and colleagues⁸⁹ extended the aortoplasty by fashioning a bifurcated, pantaloons shaped patch that straddled the commissure between the right-noncoronary leaflet, enlarging both the noncoronary and right coronary sinuses (Fig. 123-13). Concern about an untreated left coronary sinus, as well as the functional effect of an asymmetric augmentation on the aortic valve led Brom to propose a three-sinus repair.⁹⁰ A modification of this technique, proposed by Myers and colleagues⁹¹ accomplishes a three-sinus augmentation by placing counter incisions into the ascending aorta, enlarging the sinuses without prosthetic tissue.

Approximately 30% of patients will have diffuse stenosis involving the ascending aorta, sometimes with extension into the transverse arch.⁹² The diffuse form of supravulvar aortic stenosis has been shown to be an independent risk factor for death and reoperation.⁹³ When the lesion is limited to the ascending aorta, patch enlargement is usually possible using cardiopulmonary bypass. When the stenosis involves the transverse arch, deep hypothermic circulatory arrest is used to extend the patch across the entire transverse arch. Patients with lesions in the origins of the brachiocephalic vessels may require patch augmentation of these vessels as well.^{94,95}

Supravulvar aortic stenosis can also involve the coronary ostia, possibly in the form of restricted coronary inflow secondary to leaflet fusion along the narrowed and exaggerated sinotubular ridge, or less commonly because

of the encroachment on the ostial lumen by the disease. Although relief of the supravulvar stenosis treats the former, true ostial involvement may require specific attention. Modest encroachment on the coronary ostium by sinus tissue may be amenable to simple débridement, whereas severe cases may require patching of the ostium or bypass grafting.⁹⁶⁻⁹⁸

Surgical Results

There has been a gradual evolution from the single patch to the double patch, and ultimately to the three-sinus repair for the relief of discrete supravulvar aortic stenosis. In a review of 75 patients with supravulvar aortic stenosis, Stamm and colleagues⁹³ reviewed the effects of surgical technique on long-term outcomes. Comparison of the single versus multiple sinus augmentations (inverted bifurcated aortoplasty, $n = 35$; three sinus technique, $n = 6$) showed that patients undergoing single sinus augmentation had significantly higher mean gradients (20 vs. 10 mm Hg; $P = 0.008$) at a mean late follow-up of 12.8 years. Similar results have been reported by others.³⁴ Analysis has shown that single sinus augmentation is an independent risk factor for death and reoperation. These findings were independent from the year of operation (Fig. 123-14). The authors concluded that multiple sinus augmentation was superior to single sinus augmentation. It seems reasonable to expect that augmentation of all three sinuses, using techniques developed by Brom, Myers, and others may provide additional long-term advantages by allowing a more complete restoration of aortic root geometry.^{90,91}

FIGURE 123-14 ■ **A**, Comparison of long-term survival in patients with single or multiple reconstructions. **B**, Freedom from reoperation percentage by type of operation and length of time to first reoperation.

The prognosis of diffuse supravulvar aortic stenosis appears to be worse than for the discrete variant, and it has been identified as an independent risk factor for reoperation and death (Fig. 123-15).

AORTIC REGURGITATION

Isolated congenital aortic regurgitation (AR) is a rare primary lesion, and it is usually secondary to another underlying congenital lesion.⁹⁹ Most commonly, AR is the consequence of efforts designed to relieve congenital aortic stenosis.¹⁰⁰

Primary Congenital Aortic Valve Regurgitation

Primary congenital AR is rare, but it most commonly occurs in patients with a congenitally bicuspid aortic valve.¹⁰¹ In this scenario, the anterior or right coronary leaflet is often deficient or incompletely fused to one of the adjacent leaflets. Over time, the progressive AR leads to increased thickening of the leaflet edges. Another rare but important association with primary AR is a quadricuspid aortic or truncal valve.¹⁰² Myers and

FIGURE 123-15 ■ **A**, Survival rate comparison of discrete and diffuse stenosis, in years. **B**, Freedom from reoperation of discrete and diffuse stenosis, in years.

colleagues¹⁰³ have reported on 36 patients who underwent valve repair for significant truncal valve regurgitation. A quadricuspid valve had worse freedom from reoperation and tricuspidization tended to improve freedom from reoperation. Neonatal repair and leaflet thinning were independent predictors of reoperation.¹⁰³

Aortic Regurgitation Associated with a Ventral Septal Defect

Aortic regurgitation can be associated with perimembranous or subarterial VSDs. It is less common that a perimembranous VSD has associated aortic regurgitation, because the defect is generally under the commissure between the right and noncoronary leaflets. In the case of subpulmonic VSD, right coronary leaflet prolapse is more common because it is not supported with a commissure.

In the setting of a perimembranous or subarterial VSD, associated aortic valve prolapse is an indication for surgery. Eroglu and colleagues¹⁰⁴ reported that 38% of these patients with prolapse developed aortic insufficiency within 1 year. Once present, the progression of aortic insufficiency was relatively rapid, with 31% of patients progressing from mild to moderate insufficiency

FIGURE 123-16 ■ Repair of the aortic valve including plication of the aortic sinus.

within 1.1 years. VSD closure in the setting of severe aortic insufficiency is less successful than with mild or moderate aortic insufficiency. Freedom from reoperation was 64% versus 77% at 10 years ($P < 0.05$).¹⁰⁵ Thus, repair of perimembranous or subarterial VSDs presenting with aortic valve prolapse is justified, even in the setting of hemodynamically small defects.

Simple VSD closure in the face of severe prolapse and aortic insufficiency may be inadequate. In these instances, repair of the aortic valve, including plication of the aortic sinus, may be effective (Fig. 123-16). Yacoub and colleagues¹⁰⁶ reported their results in 46 such patients, with an average follow-up of 8.4 years. Under these circumstances, VSD closure with aortic sinus plication is effective and durable.

Aortic Regurgitation following Balloon Dilation for Aortic Stenosis

Aortic regurgitation is most commonly associated with catheter-based balloon dilation in patients with congenital aortic stenosis. The most common lesion is tearing of the anterior leaflet at the anterior commissure (or raphe) in a patient with a bicuspid aortic valve. Bacha and colleagues¹⁰⁷ reported the Boston Children's Hospital experience in which 20 of 21 patients had right coronary cusp involvement.

Efforts to relieve aortic stenosis early in life come at the expense of introducing AR. These patients may present acutely with severe AR or years later with ventricular dysfunction in the setting of mixed aortic valve pathology. Determining the appropriate timing for operation in these often-asymptomatic patients can be difficult, and it should be noted that there might be different guidelines depending on the surgical approach. For example, expertise in aortic valve repair may persuade one toward earlier surgical intervention at a younger age.

Cheung and colleagues¹⁰⁸ have addressed the timing of operation for AR in children. They studied a group of 21 asymptomatic young patients (median age, 13 years) with AR undergoing the Ross operation. Eighteen of these patients had previously undergone aortic valvotomy (surgical or balloon) for aortic stenosis. In their

experience, the z-score of the preoperative left ventricular end-diastolic dimension was the most sensitive predictor of postoperative left ventricular performance. Postoperative left ventricular performance was significantly impaired in patients with a preoperative z-score of 4 or greater, and the authors recommended AVR in asymptomatic patients when the left ventricular end-diastolic z-score exceeded 3.¹⁰⁸ Accepted guidelines for aortic valve intervention in the adolescent and young adult include the appearance of symptoms, asymptomatic left ventricular systolic dysfunction, or asymptomatic progressive left ventricular enlargement with z-scores greater than 4.¹⁰⁹

Aortic Regurgitation Associated with a Dilated Aortic Root

Aortic root dilation can be seen in connective tissue disorders such as Marfan and Ehlers-Danlos syndromes, conotruncal abnormalities including tetralogy of Fallot and pulmonary atresia, and in patients having undergone a Damus-Kaye-Stansel procedure with a neo-aortic valve. The regurgitation in these patients often begins central as the commissural posts at the sinotubular junction dilate with resultant leaflet stretching and prolapse.

Marfan syndrome is a systemic collagen vascular disorder that can affect the aortic valve early in life. Van Karnebeck and colleagues reported the natural history of Marfan syndrome in 52 pediatric patients (25 male) with a mean age at presentation of 7.9 years (range, 1-16 years) with median follow-up of 7.7 years (range, 2-15 years).¹¹⁰ Sixty-three percent represented familial cases, and 33% were sporadic. Aortic dilation was present in 80% of patients, and aortic regurgitation developed in 13 (25%); 10 of 13 (77%) patients required aortic operation. The authors concluded that childhood and adolescence are crucial periods in the development of the cardiovascular manifestations associated with Marfan syndrome. When the syndrome is diagnosed in the newborn period, cardiac mortality is high (33% 1-year mortality) and is reported to result from multivalve disease.^{111,112}

With the potential for aortic dissection in older patients with Marfan syndrome, attempts have been made to identify patients that would benefit from pre-emptive surgery. Leggett and others reported that an

aortic ratio (normalized for age and body surface area) of 1.3 or greater, or a rate of progression exceeding 5% per year, indicates patients at increased risk for aortic root complications.¹¹³ Cameron and colleagues¹¹⁴ have suggested that indications for aortic root replacement in children with Marfan syndrome include aneurysm diameter measuring 5 cm or greater, aneurysm diameter increasing more than 1 cm/yr, and progressive aortic valve insufficiency.¹¹⁴ Indications for surgery in young children (<12 years) include a “giant” aneurysm that meets adult criteria for intervention, and rapid interval enlargement with progressive valvar insufficiency.¹¹⁵ Using these criteria, this group reported their experience with valve-sparing aortic root replacement in 51 patients (34 with Marfan syndrome) with aortic root aneurysm and competent aortic valves. There were no deaths, and valve function remained stable during follow-up.¹¹⁶

Myers and colleagues¹¹⁷ recently reported the Boston Children’s Hospital experience of a combined valve-sparing and valve reconstruction approach over a 12-year period. Thirty-four patients were included with seven having documented connective tissue disorders, with a mean age of 15.4 ± 8.7 years. The surgery consisted of reimplantation technique in 13 patients and remodeling in 21 patients. Valve repair consisted of leaflet procedures in 25 patients and subannular reduction in 15 patients. During a mean follow-up of 14.4 ± 2.8 months, there were five reoperations for AVR because of aortic regurgitation, and two patients exhibited moderate regurgitation. Freedom from structural valve deterioration (SVD) was $75.9\% \pm 9.4\%$ at 6 months, $70.1\% \pm 10.3\%$ at 1 year, and remained stable thereafter, although it was significantly worse in the reimplantation group ($P = 0.028$). A more severe degree of aortic regurgitation ($P = 0.001$) and smaller graft-to-aortic annulus ratio ($P = 0.003$) were the only predictors of SVD.

AORTIC VALVE RECONSTRUCTIVE TECHNIQUES

Aortic valve reconstruction is particularly attractive for children with limited valve replacement options. The effectiveness of reconstructive techniques for aortic insufficiency has been variable, and it is related to the etiology of the underlying aortic valve disease. In some specific instances, such as in association with a VSD, repair can be successful and durable as noted previously. However, there are other situations in which there is complex aortic valve disease, and results have been variable.

Aortic Valve Leaflet Prolapse

There have been several techniques described for aortic valve leaflet prolapse. In addition to the original leaflet resuspension techniques described by Trussler,^{117a} Cosgrove and colleagues¹¹⁸ described a central triangular shaped wedge resection of the prolapsed leaflet, and Boodhwani and colleagues¹¹⁹ recently reported on plication of the free edge of the prolapsing leaflet.

When there is associated leaflet prolapse with a VSD, the Yacoub technique is often used. The defect can be

approached through an aortotomy, and then interrupted nonabsorbable sutures are supported with pledgets and inserted through the rightward crest of the septum, through the annulus of the aortic valve, through the redundant portion of right coronary sinus of Valsalva to achieve plication, and then through the media of the aorta.¹⁰⁶

Aortic Valve Leaflet Extensions

When aortic insufficiency results from lack of central leaflet coaptation, reparative techniques often use some variant of leaflet extension. Fixed pericardium, either bovine or autologous, has been used to extend the diseased leaflets, thereby increasing the area of coaptation. Myers and colleagues¹⁰³ compared untreated autologous, glutaraldehyde-treated bovine and PhotoFix-bovine pericardium in 78 children with rheumatic aortic valve disease. During a median follow-up of 10.7 years, 15 patients required reoperation, and fresh autologous and PhotoFix pericardium trended toward better durability than glutaraldehyde-fixed bovine pericardium did.¹⁰³

The results of aortic valve repair using leaflet extensions has been used increasingly and reported by a number of centers with acceptable early results in patients with primary congenital aortic valve disease and rheumatic disease. Polimenakos and colleagues¹²⁰ recently reported a large experience with 142 pediatric patients with primary congenital aortic valve disease undergoing pericardial aortic cusp extension valvuloplasty with a median follow-up of 14.4 years. Sixty-four patients underwent aortic valve reintervention and freedom from reoperative aortic cusp extension valvuloplasty or AVR at 18 years was $82.1\% \pm 4.2\%$ and $60\% \pm 7.2\%$, respectively. A review by Bacha and colleagues¹⁰⁷ reported on 81 pediatric patients undergoing surgical aortic valvuloplasty, including 65 undergoing aortic leaflet augmentation with pericardium. While freedom from aortic valve reintervention was only 63% at 5 years, this technique can be valuable when valve replacement options are considered unsuitable.

Others have reported results in patients primarily with rheumatic aortic valve disease. Duran and Gometza¹²¹ reported their experience with leaflet extension in 72 patients. Over a limited follow-up (≤ 5 years) there were two late deaths (2.8%) and four (5.5%) reoperations between 4 and 38 months postoperatively. Similar results have been reported by Grinda and colleagues.¹²² Among 89 patients (mean age, 16 years) undergoing leaflet extension, the 5-year survival and freedom from reoperation was 96% and 92%, respectively.

AORTIC VALVE REPLACEMENT

Aortic valve substitutes include biologic, bioprosthetic, and mechanical valves. The available options for biologic valve replacement include xenografts, homografts, and autografts. The choice of valve substitute in the pediatric population must balance several competing factors including durability, size, growth potential, and the need for anticoagulation.

Aortic Valve Replacement with Bioprosthetic Aortic Valves

Bioprosthetic valves have been used for several decades in adult patients. Experience has been accumulating in pediatric patients, but currently there are limited reports. There are several contributing factors that are clearly important to the limited longevity of bioprosthetic valves in younger patients, including patient-prosthesis mismatch (PPM) and the propensity to calcify. Flameng and colleagues¹²³ reported that PPM predicts structural valve degeneration in bioprosthetic heart valves. Additional confounding valve related factors were also found to be important, such as valve design (stented or stentless), tissue type (porcine aortic valve or bovine pericardium), and anticalcification treatments to mitigate calcification. In a large follow-up study including 648 adult patients, the absence of antimicrobial treatment and PPM were independent predictors of SVD. Freedom from SVD at 10 years was significantly worse in patients receiving a nontreated ($70\% \pm 4.3\%$) versus treated ($90\% \pm 3.6\%$) valve ($P < 0.0001$), and in patients with PPM and nontreated valves ($59.8\% \pm 7.0\%$) versus those with PPM and treated valves ($88.7 \pm 3.6\%$; $P < 0.0001$).¹²⁴ Based on this series and others, longer-term outcomes on bioprosthetic heart valves in children are needed.

Aortic Valve Replacement: Comparing Mechanical and Biologic Valves

The surgeon is faced with several options for AVR in the pediatric patient. Each option presents a unique profile of advantages, disadvantages, and performance characteristics that will be reviewed.

A major decision point in valve selection for pediatric AVR is between mechanical versus biologic (xenograft, homograft, and autograft). The early mortality of mechanical AVR is 0% to 13%, and the late mortality is 0% to 11%. The incidence of reoperation on these valves

is 6% to 16%.¹²⁵⁻¹²⁷ Patients receiving xenografts appear to have a lower mortality (early and late mortality, 0%), but a higher risk of reoperation, as approximately 50% will require repeat AVR within 6 years. In general, homografts and autografts have superior resistance to postoperative endocarditis compared with mechanical valves. Mechanical valves demonstrated a higher risk of prosthesis endocarditis in the early postoperative period that declines within 1 year, approximating the low level hazard of biologic valves.¹²⁸ The risk of endocarditis in the autograft and homograft appear comparable, and they are preferred over other prostheses in the setting of active endocarditis.

Because of their tendency to degenerate, xenograft valves have generally been avoided among pediatric patients. Turrentine and colleagues¹²⁹ compared the results of mechanical versus biological valves (autograft, homograft, and xenograft) in the aortic position. They reported a lower incidence of valve-related complications in the autograft group as compared with all other valve options. The homograft and xenograft performed particularly poorly in terms of freedom from reoperation, with 70% (7/10) xenografts and 50% (1/2) homografts requiring replacement for deterioration within 9 years (Fig. 123-17). While efforts to develop xenografts suitable for the pediatric population continues, follow-up remains short.¹³⁰ Thus, in the absence of compelling indications for their use, homografts and xenografts in the aortic position in children should probably be avoided.

Comparisons between the autograft (Ross operation) and mechanical AVR have also been reported. Following the Ross operation, Elkins has reported an 89% freedom from reoperation or death at 6 years, as compared with only 49% among children receiving a mechanical AVR.¹³¹ However, these populations were from different time periods, with the mechanical AVR being performed before 1986. A more contemporary study reported by Alexiou and colleagues¹³² reported results more consistent with those obtained with the Ross operation. They performed mechanical AVR on 56 children between 1972

FIGURE 123-17 ■ Survival (A) and freedom from reoperation (B) rates comparing mechanical and biological valve replacements in postoperative years. AH, Aortic homograft; MV, mechanical valves; PA, pulmonary autograft; XG, xenograft tissue valves.

FIGURE 123-18 ■ Freedom from late events in mechanical aortic valve replacements.

and 1999. Freedom from late events, including thrombosis, hemorrhage, and reoperation, was approximately 90% at 6 years (Fig. 123-18). This group presented excellent results with pediatric AVR, but it should be noted that the majority of these patients were older than 10 years, and 50% underwent aortic root enlargement at the time of valve insertion. There were two major (valve thrombosis, stroke) and four minor (nose bleeds) complications related to anticoagulation. Interestingly, a recent review of 45 pediatric patients receiving bileaflet mechanical aortic valves reported a 6% incidence of repeat valve replacement at 10 years, similar to that reported in many Ross operation series.¹³³

The indications for valve replacement can also affect outcomes. Lubiszewska and colleagues¹³⁴ found mechanical valves in the aortic position to be satisfactory substitutes, especially for aortic insufficiency. These children often have a normal or enlarged aortic annulus, and adult sized valves are readily accepted.

In a review of 51 patients undergoing AVR (25 mechanical, 19 autografts, 6 homografts), Lupinetti and colleagues¹³⁵ reported a significantly higher incidence of late complications in those receiving a mechanical valve. The most common long-term complication reported in this group was the development of subaortic stenosis because of pannus ingrowth. Others have also reported significant numbers of anticoagulation related complications. Cabalka and colleagues¹³⁶ reported six serious complications among 36 patients undergoing isolated AVR between 1982 and 1994, with all occurring in the setting of supratherapeutic prothrombin times. Freedom from anticoagulation-related bleeding for isolated AVR was approximately 80% at 4 years.

We recently reviewed our experience at Boston Children's Hospital from 2004 to 2013, during which time 38 patients underwent AVR with the On-X prosthetic valve (On-X Life Technologies, Inc., Austin, TX). During a

median follow-up of 4.3 years, there was no evidence of structural valve failure or deterioration, no patients had greater than mild prosthetic valve regurgitation, and one patient had moderate stenosis. No patients had evidence of valve thrombosis, embolism, or other bleeding complications. Survival was $98\% \pm 1.9\%$ at 1 year and $91.3\% \pm 5\%$ at 5 and 8 years, and it was significantly better in patients with isolated AVR ($P < 0.001$).

Aortic Valve Replacement: Comparing Autografts and Homografts

Homografts share some of the advantages provided by the autograft, but they also present serious disadvantages. Besides a lack of growth potential, early degeneration requiring replacement has been documented, especially among young patients, and some authors have reported inferior hemodynamics as compared with autograft.^{137,138} This has led some investigators to compare outcomes of the Ross procedure with its most comparable alternative, the homograft.

In the earliest and largest series comparing the autograft to homografts in young patients, Gerosa and colleagues¹³⁹ compared the results of 103 young patients receiving a homograft in the aortic position to 43 receiving an autograft. The 15-year freedom from reoperation was $54\% \pm 8\%$ versus $68\% \pm 11\%$, freedom from endocarditis was $97\% \pm 2\%$ versus $75\% \pm 10\%$, and freedom from any complication was $41\% \pm 7\%$ versus $50\% \pm 10\%$. Primary tissue failure was identified in 19 homografts, but in none of the autografts.

Aklog and colleagues¹⁴⁰ examined the performance of these two options in a prospective randomized trial. A total of 182 patients were randomized, with a mean age of 37 years (range, 2-64 years). Ninety-seven patients received a pulmonary autograft, and 85 patients received a homograft. Thirty-day mortality was 1% for autografts and 4% for homografts, and actuarial survival was 97.8% and 95.3% at 48 months, respectively. There were no autograft-related reoperations. Freedom from reoperation was slightly higher in the autograft group (94.2% vs. 87.7%; $P = \text{NS}$). Regarding the pediatric age group, they reported that 2 of 6 (33%) children required reoperation on the homograft, compared with 0 of 10 in the autograft group. Furthermore, there was echocardiographic evidence of progressive, subclinical deterioration in the homograft group that was absent in the autograft group. The authors concluded that the autograft appeared to be superior in the pediatric population, and they suggested that longer follow-up will reveal a continued durability advantage.

Lupinetti and colleagues¹⁴¹ examined the comparative effects of autografts and homografts on left ventricular remodeling in the pediatric population. While the authors reported that initial LVOT gradients and left ventricular wall thickness (surrogates for hemodynamic efficiency) were comparable among 78 children undergoing the Ross operation and 25 receiving a homograft, a divergence was noted over time. Whereas peak LVOT velocities decreased over time after the Ross operation, they increased significantly over a similar time period in the homograft group. The decrease in left ventricular wall

thickness seen in those undergoing the Ross operation was absent in the homograft group. This effect may be most important in young patients in whom significant somatic growth can be expected.

Thus, while the homograft may provide acceptable palliation among older patients, its lack of durability appears to be a serious disadvantage, especially among younger children. Under these circumstances, its use should probably be relegated to an option for children deemed unsuitable for the autograft or a mechanical valve.

Aortic Valve Replacement with the Pulmonary Autograft (Ross Operation)

The transplantation of the pulmonary valve to the aortic position, introduced by Donald Ross in 1967, has several potential advantages over other valve replacement options in pediatric patients.¹⁴² Most notably among children, the growth potential of the autograft is a unique feature, especially in the infant population in which small caliber homografts are the only alternative. In addition, superior hemodynamics are obtainable, and there is no need for systemic anticoagulation.

The autograft may be inserted into the aortic position using a variety of techniques, including the subcoronary technique, the root inclusion technique, or the root replacement technique. Excellent reviews of each technique are available.^{143,144} The autograft root replacement is usually performed with bicaval cannulation. The aortic valve is inspected and if irreparable, the pulmonary artery is opened at the bifurcation. The pulmonary valve is inspected, and valves with important anatomic abnormalities (bicuspid valve, significant leaflet fenestrations) are not suitable for use in the aortic position, and an alternative valve replacement is chosen. Small leaflet fenestrations, particularly near the valve commissures, are probably acceptable.

The autograft is excised with a rim of infundibular muscle. Posteriorly, care must be taken to avoid the first septal perforator, because significant ventricular dysfunction may accompany its injury. After débridement of the aortic annulus, the autograft is oriented anatomically and sutured into the aortic position. The coronary arteries are inserted into the appropriate sinus, and the distal anastomosis between the autograft and the ascending aorta is performed. The RVOT is reconstructed with the aid of a cryopreserved homograft. Although some groups have advocated direct approximation of the pulmonary arteries to the right ventricle (similar to the REV technique), oversized homografts provide excellent durability and are probably a superior option.¹⁴⁵ Disadvantages of the Ross operation include increased technical complexity, homograft reconstruction of the RVOT, and potential autograft failure.

Elkins has reported his midterm and late results with the Ross operation between 1986 and 2001.¹⁴⁶ Operative mortality was 4.5%, with a 12-year actuarial survival of $92\% \pm 3\%$. Actuarial freedom from autograft replacement and from RV homograft replacement was $93\% \pm 3\%$ and $90\% \pm 4\%$ at 12 years, respectively. Most contemporary series place the operative mortality between

0% and 4%.¹⁴⁷⁻¹⁵⁰ Because of the low mortality and effectiveness of the Ross operation, it has become the procedure of choice at some institutions.

In a recent large series reported by Pessotto and colleagues,¹⁴⁸ 67 children underwent the Ross operation. Two neonates (2/67, 3%) undergoing a Ross-Konno procedure after a failed attempt at balloon dilation for critical aortic stenosis died of multisystem organ failure. Two patients (2/67, 3%) have required reoperation for progressive autograft insufficiency; in one patient, annular reduction was successful in salvaging the autograft.

The question of durability is a concern that continues to be examined. The longest follow-up to date has been reported by Chambers and Ross,¹⁵¹ who described the experience of the 131 hospital survivors undergoing the Ross operation between 1967 and 1984. Of the survivors, they reported that the freedom from autograft replacement was 88% at 10 years and 75% at 20 years. Interestingly, this was similar to freedom from reoperation on the RVOT (89% and 80%). Of the 30 autografts explanted, only three showed histologic signs of focal degenerative changes. All others showed evidence of transmural cellular viability.

In a recent pediatric series, conflicting information has been emerging. While Brown and colleagues¹⁵² have reported a low incidence of autograft failure requiring replacement at 10 years (4%), others have reported autograft failure rates as high as 31% at 13 years.¹⁵³ While the long-term fate and patient selection criteria remain an area of investigation, the Ross operation remains an important option for the pediatric patient with severe aortic valve disease.

Contraindications to the Pulmonary Autograft (Ross Operation)

The Ross operation requires careful patient selection. Systemic collagen vascular disorders and anatomic abnormalities of the pulmonary valve constitute a clear contraindication to the Ross operation. Others have also suggested that the Ross operation should be avoided in the setting of systemic inflammatory conditions, such as rheumatoid arthritis, lupus, and rheumatic heart disease.¹⁵⁴⁻¹⁵⁶ There have been mixed results in patients with bicuspid aortic valve disease.

Al-Halees and colleagues¹⁵⁷ reviewed their results with 78 patients undergoing the Ross operation in the Middle East. Eighty percent of these patients suffered from rheumatic disease of the aortic valve, and 28% had significant mitral regurgitation. Five (8%) of these patients have required reoperation between 20 and 26 months postoperatively—four for autograft failure and one for recurrent mitral regurgitation. One autograft demonstrated histologic evidence of valvulitis consistent with rheumatic disease. Choudhary and colleagues¹⁵⁸ performed the Ross operation in 75 patients suffering from rheumatic aortic valve disease. Two patients required reoperation for autograft failure, and 13 showed evidence of moderate or severe autograft insufficiency, with leaflet thickening, generally between 12 and 24 months after operation. Autograft function was significantly inferior in rheumatic patients.

Bicuspid aortic valve disease is considered to be contraindication for the Ross procedure by some; however, the data remain controversial. Examining the pulmonary trunk in patients with bicuspid aortic valve disease, de Sa and colleagues¹⁵⁹ reported histologic evidence of cystic medial necrosis, elastic fragmentation, and smooth muscle cell abnormalities. They suggested that these findings manifest themselves as subsequent autograft dilation; however, conflicting results have also been reported. Luciani and colleagues¹⁶⁰ have reported no histopathology of the pulmonary trunk in the setting of bicuspid aortic valve disease, and they noted no greater tendency for autografts in this setting to dilate. Likewise, in a large pediatric experience, Elkins and colleagues^{161,162} reported that preoperative aortic regurgitation, but not valve morphology, was associated with autograft degeneration.

PROSTHETIC MECHANICAL VALVES, ANTICOAGULATION, AND PREGNANCY

Prosthetic valves, systemic anticoagulation, and pregnancy are important issues for young women with aortic valve disease. Edmunds reported that women with mechanical valves were at risk for thrombotic complications if anticoagulation were interrupted.¹⁶³ However, it has been suggested that up to 30% of fetuses exposed to warfarin between the sixth and ninth weeks of gestation will develop warfarin embryopathy (nasal hypoplasia, stippled epiphyses).¹⁶⁴ Warfarin exposure during the second trimester has been implicated in central nervous system abnormalities in approximately 3% of fetuses.¹⁶⁵ In 1994, major European centers were queried about the clinical approach to anticoagulation, prosthetic valves, and pregnancy.¹⁶⁶ There were 214 pregnancies in 182 women, 151 pregnancies in 133 women with mechanical valves, and 63 pregnancies in 45 women with bioprosthetic valves. Including abortions (spontaneous and therapeutic), 83% of pregnancies among women with bioprosthetic valves, and 73% of pregnancies among women with mechanical prosthesis, resulted in healthy children, consistent with other reports.¹⁶⁷

Anticoagulation was administered in 150 of the 151 pregnancies among 133 women with mechanical valves. Thirty-four women received subcutaneous heparin throughout the pregnancy, 50 received warfarin for the duration of gestation, and 66 received subcutaneous heparin for the first trimester and warfarin thereafter. Warfarin was discontinued, and subcutaneous heparin was restarted 2 to 4 weeks before the estimated date of confinement. No cases of warfarin embryopathies were reported. There were 13 mechanical valve thromboses; 12 of these were in the mitral position, and 10 were taking heparin ($P < 0.05$). The single woman suffering aortic valve thrombosis refused all anticoagulation and died from valve thrombosis. Of the seven major bleeding complications, five occurred in women taking heparin and two were in women taking warfarin ($P < 0.05$). The incidence of spontaneous abortions did not differ between the two groups (10% and 12%). Among the 45 women with bioprosthetic valves, pregnancy tended to accelerate

deterioration of these valves. Thirty-one percent of these women required replacement during pregnancy or shortly thereafter.

More recent series reporting on large numbers of pregnancies in women receiving warfarin for prosthetic valves suggest that the risk of warfarin embryopathy may be overstated, and the incidence of spontaneous abortion, thromboembolic episodes, or bleeding have been shown to be similar to those among women treated with heparin during the first trimester.^{168,169} However, warfarin dosages, but not the international normalized ratio [INR], were found to influence fetal outcomes.¹⁷⁰

In conclusion, these authors suggested that mechanical valves were preferable in women of childbearing potential and that oral warfarin therapy for the duration (except the last 2 weeks) was appropriate.

Potential discrepancies between these two bodies of data may be related to techniques used for monitoring warfarin anticoagulation. In the early 1990s, the United States adopted the INR (patient's prothrombin time divided by the control time using the thromboplastin standard of the World Health Organization). Before the adoption of INR, the use of thromboplastins of low responsiveness may have contributed to over-anticoagulation, equivalent to INRs of up to 9 in some preparations.^{171,172} Warfarin embryopathy is thought to be a dose-related phenomenon, and may have been exacerbated by these discrepancies.

Finally, the Ross operation has been proposed as an excellent option for young women anticipating future motherhood. In a retrospective review of pregnancy in 8 women following the Ross operation, there were 14 uncomplicated pregnancies and no deterioration in autograft function during or after the pregnancies.¹⁷³

SUMMARY

Congenital aortic valve disease is a progressive, lifelong condition that can be palliated, but not cured. The surgical management of congenital disease of the aortic valve and root remains challenging. In general, there has been a movement away from indirect surgical therapies (e.g., apical-aortic conduits) toward more direct surgical procedures designed to address the pathology directly (e.g., valve repair, Konno-Rastan, modified Konno, Ross operation). Despite the development of techniques designed to relieve stenosis at all levels, the ultimate success of palliation will often depend on the suitability of associated left heart structures.

Areas such as patient selection (particularly in the neonatal population), evolving aortic valve repair techniques, and the long-term results of procedures such as the Ross operation remain areas of investigation. The development of catheter-based interventions designed to treat specific forms of aortic root and valve pathology will continue. Lifelong surveillance is mandatory to provide long-lasting preservation of left ventricular function.

OUTCOMES

This chapter discusses the management of coronary artery anomalies in patients without other congenital heart defects. Most coronary artery anomalies in number, origin, and distribution are of intellectual interest only. However, a few are clinically significant because they may result in myocardial ischemia, left ventricular dysfunction, and sudden death. Anomalies discussed in this chapter include anomalous origin of a coronary artery from the pulmonary artery, anomalous coronary artery that courses between the aorta and pulmonary artery, coronary artery fistula, and congenital atresia of the left main coronary artery.

In normal coronary anatomy, two coronary arteries arise from separate ostia in the right and left aortic sinuses

of Valsalva. The left main coronary artery (LMCA) originates from the left aortic sinus and usually bifurcates into the left anterior descending coronary artery (LAD) and the left circumflex coronary artery. The LAD runs in the anterior interventricular groove, and the left circumflex coronary artery courses in the left atrioventricular groove. The right coronary artery (RCA) originates anteriorly from the right aortic sinus, runs along the right atrioventricular groove, and usually gives rise to the posterior descending artery at its terminus.

In most individuals, each coronary artery ostium is located centrally in the appropriate sinus of Valsalva. In some patients, the ostium may be eccentrically located, and in others a coronary artery may arise close to a valve

BOX 124-1 Origin of Both Coronary Arteries from One Sinus

1. Left main coronary artery originates from right sinus of Valsalva (either from right coronary artery or separate ostia).
Left main coronary artery courses anterior to pulmonary artery.
Left main coronary artery courses through interventricular septum.
Left main coronary artery courses between aorta and pulmonary artery.
Left main coronary artery courses posterior to aorta.
In rare cases, the left anterior descending coronary or left circumflex coronary artery alone may originate from the right sinus.
2. Single left main coronary artery arises from the left sinus and bifurcates into the left anterior descending coronary and left circumflex coronary arteries. The left circumflex coronary artery crosses the crux and continues as the right coronary artery.
3. Single right coronary artery from sinus, which crosses crux, continues as left anterior descending coronary and left circumflex coronary artery.
4. Right coronary artery originates from left sinus of Valsalva (either from left main coronary artery or as separate ostium).
Right coronary artery courses posterior to aorta.
Right coronary artery courses interior anterior to pulmonary artery.
Right coronary artery courses between aorta and pulmonary artery.

commissure. One or both coronary ostia may arise from the tubular aorta above the sinotubular junction, which is usually a benign finding. However, this high take-off of the coronary artery becomes significant if an aortotomy is necessary for aortic valve replacement or for another indication; if not recognized, the coronary artery could be transected. Another anomaly is when both coronary arteries arise from the same aortic sinus with either a single ostium or two separate ostia (Box 124-1). This is generally not clinically significant if the aberrant vessel courses posterior to the aorta or anterior to the pulmonary artery, but it becomes important if either the aberrant LMCA or RCA courses between the two great vessels, because this may lead to myocardial ischemia and sudden death.

ANOMALOUS ORIGIN OF A CORONARY ARTERY FROM THE PULMONARY ARTERY

Anomalous origin of a coronary artery from the pulmonary artery is a rare congenital anomaly that is almost always fatal if not diagnosed and treated.^{1,2} Although anomalous origin of the LMCA from the pulmonary artery (ALCAPA) is the most common, other coronary arteries may rarely also arise from the pulmonary artery. The RCA arises from the pulmonary artery approximately 10 times less frequently than ALCAPA but is also

FIGURE 124-1 ■ The aorta and pulmonary artery showing anomalous origin of the left main coronary artery from the posterior-facing sinus of the pulmonary artery with the anomalous artery coursing behind the pulmonary artery. (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. In Kaiser LR, Kron IL, Spray TL, editors: *Mastery of cardiothoracic surgery*, Philadelphia, 1998, Lippincott-Raven, p 881.)

associated with ischemia and sudden cardiac death. The LAD, the circumflex, or both the left and right coronary arteries may arise from the pulmonary artery; these variants are extremely rare and are almost uniformly fatal.

ALCAPA is the most important congenital coronary artery anomaly in this class. The incidence of ALCAPA ranges from 1 in 30,000 to 1 in 300,000 people. It is the most common cause of myocardial infarction in childhood. If not diagnosed and treated, the mortality rate is 90% by age 1 year. ALCAPA is otherwise known as the Bland-White-Garland syndrome, after Bland and colleagues reported on both clinical and autopsy findings in an infant with this anomaly in 1933.³

Anatomy

In ALCAPA, the LMCA usually arises from the main pulmonary artery (MPA); occasionally, it arises from the right pulmonary artery. It usually originates from the rightward aspect of the posterior (facing) sinus of the MPA (Figs. 124-1 and 124-2), but it may also originate from the leftward aspect of the posterior (facing) and, in rare cases, from the anterior (nonfacing) sinus of

FIGURE 124-2 ■ **A**, Anomalous origin of the left main coronary artery from the rightward aspect of the posterior-facing sinus of the pulmonary artery. **B**, Anomalous origin of the left main coronary artery from the leftward aspect of the posterior-facing sinus. **C**, Anomalous origin of the left main coronary artery from the nonfacing sinus of the pulmonary artery. (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. In Kaiser LR, Kron IL, Spray TL, editors: *Mastery of cardiothoracic surgery*, Philadelphia, 1998, Lippincott-Raven, p 882.)

the MPA (see Fig. 124-2). An anomalous RCA most commonly originates from the anterior portion of the pulmonary artery.

Although ALCAPA usually occurs in isolation, other associated cardiac defects include patent ductus arteriosus (PDA), ventricular septal defect (VSD), coarctation of the aorta, and tetralogy of Fallot.

Pathophysiology

Children with ALCAPA usually develop symptoms after closure of the ductus arteriosus and the subsequent fall in pulmonary vascular resistance. During fetal life, the systemic and pulmonary circulation pressures are similar, and myocardial perfusion remains intact because the pulmonary arterial pressure is systemic. After birth but before ductal closure, the pulmonary artery pressure remains elevated, thereby maintaining perfusion of the anomalous coronary artery. This explains why children are rarely diagnosed with ALCAPA in the first few days of life. The clinical course after ductal closure is largely determined by the presence or absence of collaterals from the RCA to the left coronary system. If there is inadequate collateral circulation, myocardial ischemia and ventricular dysfunction result from insufficient myocardial perfusion.⁴ This occurs because of subsystemic pulmonary artery pressure, and the left ventricle is thus perfused with desaturated blood at a low pressure. However, if the pulmonary artery pressure remains elevated because of the presence of another cardiac defect, such as PDA or VSD, left ventricular perfusion pressure may be adequate to prevent ischemia. If this coronary anomaly is unknown before the catheter or surgical closure of these defects, it will become apparent shortly after closure because of the subsequent drop in pulmonary arterial pressure—usually with a fatal outcome.

Alternatively, if there is adequate collateralization, perfusion of the left coronary system is maintained. As the pulmonary vascular resistance falls, however, a left-to-right shunt develops from the RCA to the pulmonary artery. There is progressive dilation of the RCA and left coronary artery systems, with reversal of flow in the left coronary leading to a pulmonary-coronary steal. Although the shunt is relatively small compared with overall cardiac

output, it is significant with regard to coronary blood flow. Children with extensive collaterals may survive past infancy; however, there is usually progressive left ventricular dysfunction.⁵ In a small percentage of cases, the collateral vessels are enough to maintain adequate myocardial perfusion at rest and sometimes even during exertion, and these patients may not come to clinical attention until adulthood.⁶ In most children, however, severe mitral regurgitation is present secondary to papillary muscle dysfunction and ventricular dilation.

Clinical Presentation

Infants frequently present between 4 and 6 weeks of age after the pulmonary vascular resistance has dropped.⁷ However, infants may not be diagnosed until 2 to 3 months of age, when symptoms have increased in severity. Infants usually show signs and symptoms of congestive heart failure, including sweating and discomfort with feeding, tachypnea, poor weight gain, and pallor. The discomfort with feeding most likely represents myocardial ischemia. Children who do not present when they are infants may be diagnosed in later infancy as a result of the loud murmur of mitral regurgitation. Older children, adolescents, and adults may remain asymptomatic, whereas others may come to clinical attention because of exertional chest pain, pre-syncope, or syncope. There have been reports of sudden death with exercise in these older patients. The symptoms associated with anomalous origin of the RCA from the pulmonary artery are less severe, but myocardial ischemia and death can still occur.

Physical examination of the infant with ALCAPA may reveal signs of congestive heart failure, including tachypnea, tachycardia, and hepatomegaly. Left ventricular dysfunction caused by ALCAPA can be difficult to distinguish from a dilated cardiomyopathy. The left heart is usually enlarged, often with associated mitral regurgitation, and a gallop rhythm also may be present. If left heart failure has resulted in pulmonary hypertension, then there may also be evidence of right heart enlargement and an accentuated pulmonary component of the second heart sound on examination.

Infants with ALCAPA generally have an enlarged cardiac silhouette on chest radiograph, resulting mainly

from the enlarged left atrium and left ventricle. In infants with congestive heart failure, the electrocardiogram (ECG) can provide a useful diagnostic clue because there are classic findings of Q waves and ST-segment elevation in leads I, aVL, and V4-V6 as a result of lateral or anterolateral wall infarction. Although this pattern can be found in other causes of myocardial infarction or cardiomyopathy, if these electrocardiographic abnormalities are seen in an infant with congestive heart failure, the diagnosis of ALCAPA needs to be strongly considered. Certainly, any infant diagnosed with dilated cardiomyopathy must be extensively evaluated for ALCAPA. This diagnosis should also be considered in older children and adolescents with a dilated cardiomyopathy, because occasional patients survive past infancy.

Diagnostic Imaging

Echocardiography with color flow Doppler usually demonstrates a dilated left ventricle with severe mitral regurgitation. The mitral regurgitation commonly seen with ALCAPA is caused by infarction of the posterior leaflet of the mitral valve and subsequent poor movement of the leaflet; fibrosis and fibroelastosis of the papillary muscle also can be present. Imaging of the coronary arteries, including origin and course, has become possible as a result of improved echocardiographic techniques, but it can still be challenging. An enlarged RCA is almost always present and should raise suspicion of this diagnosis. Careful attention should be paid to the origins of both coronary arteries, including the abnormal origin of the LMCA to the pulmonary artery. If visualization of the anomalous vessel is unclear, color flow Doppler may reveal retrograde flow from the coronary artery to the pulmonary artery. However, underdiagnosis by echocardiography is relatively common; thus, if any question remains about visualization of both coronary ostia, then cardiac catheterization is mandatory to rule out ALCAPA.

Cardiac catheterization with angiography remains the gold standard in the diagnosis of ALCAPA. Cardiac catheterization demonstrates elevated filling and pulmonary arterial pressures and a low cardiac output. In older asymptomatic patients, it may show only mildly elevated pulmonary arterial pressures but normal filling pressures and cardiac output. A small left-to-right shunt may be present. An aortogram will demonstrate a single, dilated RCA arising normally from the aorta. If significant collaterals are present, aortic root angiography will show the collaterals providing late, retrograde filling of the left coronary artery with a blush of contrast subsequently filling the MPA. If there is a large left-to-right shunt from the collaterals, a step-up in oxygen saturation may be noted in the MPA. If doubt remains regarding the diagnosis, a main pulmonary arteriogram with distal balloon occlusion should demonstrate the anomalous left coronary artery.⁸

Magnetic resonance imaging (MRI) has emerged as a useful noninvasive diagnostic tool for delineating congenital coronary anomalies.^{9,10} Although there have been case reports of using this method in diagnosing ALCAPA, no case series with this anomaly have been reported. However, studies have shown that magnetic resonance

angiography has a similar sensitivity and specificity when compared with coronary angiography and may be especially helpful in delineating the proximal course of anomalous coronary arteries. Computed tomography (CT) has been used extensively for coronary artery delineation in adults. Advantages of this technique include rapid acquisition time and high resolution, but the disadvantages include radiation exposure and the need for a slower heart rate with ECG gating, precluding its use in infants.

Surgical Management

Indications for Surgery

Surgical repair is indicated in all patients with ALCAPA. In infants with congestive heart failure, surgery should occur within the first few days of diagnosis because risk of continuing myocardial ischemia and death is very high.¹¹ In older patients who present without symptoms, surgery is necessary but can be performed electively. In an infant who presents in severe heart failure secondary to myocardial infarction, surgery will probably need to be delayed for at least 24 hours to stabilize the patient using mechanical ventilation, inotropic support, and vasodilators, when necessary. Del Nido and colleagues reported that even in the sickest infants, a two-vessel surgical repair is possible if left ventricular assist devices (LVADs) are used postoperatively.¹² Others may need extracorporeal membrane oxygenation (ECMO). Because infants requiring surgery are often quite ill, it is important that centers performing ALCAPA surgery have these options available, or else the child should be transferred to a hospital with these capabilities.

The goal of surgery is restoration of a two-coronary system; therefore, simple ligation of the anomalous coronary should not be performed.¹³ Severe left ventricular dysfunction and mitral insufficiency are not contraindications to revascularization in infants, because significant recovery of function usually occurs. Because the severity of mitral regurgitation almost always decreases after revascularization, left ventricular aneurysmectomy and mitral valve repair or replacement are rarely indicated at the time of initial procedure, even if severe mitral regurgitation is present.

Surgical Techniques

The first successful operation for correction of ALCAPA was simple ligation of the anomalous artery at the pulmonary artery. Ligating the anomalous vessel prevents the left-to-right shunt, thereby allowing perfusion of the left ventricle through collaterals from the RCA. Because of the early mortality rates and increased risk of late sudden death with this procedure, a variety of techniques have been developed to create a dual coronary artery system, including coronary artery bypass grafting, aorto-pulmonary window, and direct reimplantation.

Bypass grafts were accomplished using the left subclavian artery, the internal mammary artery (IMA), and the saphenous vein. Meyer and colleagues reported the first successful left subclavian artery-to-left coronary artery bypass in 1968.¹⁴ The results of bypass grafting, especially

with saphenous vein grafts, have been disappointing. Takeuchi and associates were the first to describe the creation of an aortopulmonary window and intrapulmonary artery baffle using a pulmonary artery flap to direct blood flow from the aorta to the anomalous coronary artery.¹⁵ Finally, the procedure of choice in many institutions has become direct reimplantation of the anomalous coronary onto the aorta, as experience with the arterial switch operation for transposition of the great vessels has increased.^{16,17}

Coronary Artery Bypass Grafting. Coronary artery bypass grafting is rarely used in patients with ALCAPA. In the current era, it is usually used to create a dual coronary artery system after previous ligation or because of stenosis or occlusion after a previous attempt at repair. The IMA is the conduit of choice and can be used successfully, even in neonates and infants; in addition, there is some evidence for growth of the IMA after bypass grafting.¹⁸⁻²⁰ The saphenous vein should not be used unless it is the only conduit available, because of the risk of occlusion and poor long-term results.²¹ Similarly, left subclavian-to-left coronary artery anastomosis is infrequently used because of the risk of anastomotic stenosis or occlusion.^{22,23}

Direct Reimplantation. In most patients with ALCAPA, direct reimplantation of the anomalous coronary artery onto the aorta can be performed (Fig. 124-3).^{24,25} When the anomalous coronary ostium is in the posterior-facing sinus, the procedure is fairly straightforward. Direct implantation is possible even if the ostium is located in the nonfacing sinus by excising a large button of pulmonary artery to extend the coronary artery.

After induction of anesthesia and placement of monitoring lines, a median sternotomy is performed. The thymus is resected. The pericardium is opened and suspended in stay sutures. Because of the likelihood of myocardial ischemia and left ventricular dysfunction, there is a risk of ventricular fibrillation, so contact with the myocardium should be kept at a minimum until the patient is placed on cardiopulmonary bypass. This operation may be performed using either continuous low-flow bypass with moderate hypothermia (25° to 28° C) or deep hypothermic circulatory arrest (18° C) in very small infants. Before cannulation, an aortic purse-string suture is placed distally near the innominate artery, and another is placed in the right atrial appendage for a single venous cannula. Heparin is administered, the aortic and right atrial cannulas are inserted, and cardiopulmonary bypass is established. The left ventricle should be decompressed by placing a left ventricular vent via the right superior pulmonary vein. The pulmonary artery and epicardial course of the left coronary artery are visualized. If the anomalous left coronary artery originates far leftward in the posterior-facing sinus or on the anterior nonfacing sinus, direct reimplantation may not be possible.

The aorta and both pulmonary arteries are fully mobilized. To improve mobility of the pulmonary artery, the ductus (or ligamentum) arteriosus is ligated. Tourniquets are placed around both the right and the left branch pulmonary arteries to occlude the branch pulmonary

FIGURE 124-3 ■ After institution of cardiopulmonary bypass and induction of cardioplegia, the pulmonary artery is transected above the sinotubular junction, and the anomalous coronary ostium is excised with a generous button of pulmonary artery wall. (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. In Kaiser LR, Kron IL, Spray TL, editors: *Mastery of cardiothoracic surgery*, Philadelphia, 1998, Lippincott-Raven, p 883.)

arteries and prevent runoff of cardioplegia solution into the lungs. Another option to prevent runoff is to compress the origin of the coronary artery from the pulmonary artery during administration of cardioplegia solution. A cannula is inserted in the ascending aorta for administration of cardioplegia solution, the aorta is cross-clamped, and cold cardioplegia is administered via the aortic root. If circulatory arrest is used, the head vessels are then occluded with tourniquets after adequate cooling, the circulation is arrested, venous blood is drained into the reservoir, and the cannulas are removed. After adequate arrest, the pulmonary artery is transversely opened just above the sinotubular junction (see Fig. 124-3). The anomalous coronary orifice is identified. The pulmonary artery is divided and the coronary ostium is excised from the pulmonary artery with a generous button of arterial wall, as in the procedure used for the arterial switch operation. The segment of the pulmonary wall that is excised extends the proximal end of the coronary artery, thus allowing the aortic anastomosis to be accomplished without tension. To excise the coronary button, the pulmonary commissure may need to be taken down if the coronary ostium is located near a commissure. An alternative technique that can be used if the coronary arises anteriorly from the pulmonary artery or from a branch pulmonary artery involves extension of the coronary artery with a tube constructed from pulmonary artery wall to allow reimplantation (Fig. 124-4). The proximal portion of the coronary artery is mobilized with cautery, using caution to avoid any small branches. As in the arterial switch operation, the aorta is then opened transversely immediately above the sinotubular junction, and

FIGURE 124-4 ■ Occasionally when the coronary artery arises from the leftward or anterior aspect of the pulmonary artery, direct reimplantation may not be possible. In these situations, a tube can be constructed from a segment of pulmonary artery to lengthen the coronary and allow reimplantation on the aorta. (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. In Kaiser LR, Kron IL, Spray TL, editors: *Mastery of cardiothoracic surgery*, Philadelphia, 1998, Lippincott-Raven, p 883.)

the incision is carried posteriorly above the left posterior sinus (Fig. 124-5). The sinus is then incised vertically to accept the coronary button. The coronary button is carefully aligned with the aortic incision to avoid twisting or kinking. A continuous suture of 7-0 polypropylene (Prolene) is used to start the anastomosis at the most inferior aspect of the coronary button, which is attached to the most inferior aspect of the incision in the sinus. The suture line is carried to the top of the incision anteriorly and posteriorly. The aorta is closed with a continuous suture of 7-0 Prolene, which is tied to the coronary button suture as the anastomosis is completed (see Fig. 124-5). Once the aorta has been closed, cardioplegia solution is administered and the anastomotic site is inspected for adequate filling of the coronary and for hemostasis. Occasionally, the anomalous artery may arise from the right pulmonary artery and run along or within the aortic wall to the sinus. If there is a common wall with the aorta, mobilization may not be possible. In this case, unroofing of the intra-mural segment should be performed.²⁶

In some cases, the pulmonary artery can be repaired primarily with a continuous suture of 7-0 Prolene (Fig. 124-6). The ductus should be divided to improve mobility of the pulmonary artery confluence, thus allowing reconstruction without tension. However, more often, the pulmonary artery is repaired with a patch of autologous pericardium (see Fig. 124-6). If a commissure was taken down during excision of the coronary button, the pulmonary artery should be reconstructed with pericardium and the commissure resuspended.

The patient is rewarmed and the aortic cross-clamp is removed. The cross-clamp may be removed before the pulmonary artery reconstruction to minimize ischemia

FIGURE 124-5 ■ After the anomalous coronary artery is mobilized, the aorta is opened transversely above the sinotubular junction and a vertical incision is made in the left posterior sinus to accept the reimplanted coronary. (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. In Kaiser LR, Kron IL, Spray TL, editors: *Mastery of cardiothoracic surgery*, Philadelphia, 1998, Lippincott-Raven, p 884.)

FIGURE 124-6 ■ After the coronary is reimplanted, the aorta is closed primarily. The pulmonary artery may often be closed primarily. Ligation and division of the ligamentum arteriosus improves mobility of pulmonary artery. Occasionally, patch repair of the defect in the pulmonary artery with autologous pericardium may be necessary (*inset*). (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. time. The left ventricle is inspected to assess for adequate perfusion and function, and suture lines are inspected for hemostasis. Right and left atrial lines are placed to adequately monitor pressure and for drug administration. Atrial and ventricular pacing wires are also placed. The patient is separated from cardiopulmonary bypass after complete rewarming. Attention should be paid to the ECG during reperfusion and after separation from bypass for evidence of ischemia. Inotropic support may be necessary temporarily if there was left ventricular dysfunction preoperatively.

Modified Takeuchi Operation. The Takeuchi operation, or intrapulmonary artery tunnel, is an alternative surgical strategy for repair of ALCAPA. Originally, Takeuchi and colleagues described the creation of an aortopulmonary window using a portion of anterior pulmonary artery wall to form a baffle that would direct blood from the aorta to the ostium of the anomalous coronary artery.¹⁵ In the modified repair, the baffle is constructed using a polytetrafluoroethylene (PTFE) (Gore-Tex) patch. Creating a baffle may not be possible if the ostium is located near a commissure or arises from a branch pulmonary artery. The procedure may be performed with either continuous low-flow cardiopulmonary bypass (25° C to 28° C) or deep hypothermic circulatory arrest (18° C). Cannulation is performed as for direct reimplantation.

After induction of cardioplegia, a longitudinal incision is made in the anterior portion of the pulmonary artery (Fig. 124-7), and the ostium of the anomalous coronary

FIGURE 124-7 ■ After institution of cardiopulmonary bypass and induction of cardioplegia, a longitudinal incision is made in the main pulmonary artery, and the ostium of the abnormal coronary is identified. (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. FIGURE 124-8 ■ Using a punch, a 5-mm opening is made in the aorta on the leftward aspect above the sinotubular junction. A similar opening is made in the pulmonary artery at the same level, and these are anastomosed to create an aortopulmonary window. (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. In Kaiser LR, Kron IL, Spray TL, editors: *Mastery of cardiothoracic surgery*, Philadelphia, 1998, Lippincott-Raven, p 885.)

is identified. Using a punch, a 5-mm diameter opening is made on the leftward aspect of the aorta above the sinotubular junction (Fig. 124-8). An anterior aortotomy should be performed if there is any question about placement of the aortic opening, and the incision should be directly visualized to avoid damage to the aortic valve. Creating the aortopulmonary window above the sinotubular junction allows a downward angle of the baffle into the sinus if the ostium is located deep in a sinus. After a similar incision is made in the pulmonary artery directly opposite the opening in the aorta, these are anastomosed using a continuous suture of 7-0 Prolene and creating an aortopulmonary window (see Fig. 124-8). A 4-mm PTFE tube graft is split longitudinally and customized to an appropriate length (Fig. 124-9). This graft acts as an intrapulmonary artery tunnel, baffling blood from the aortopulmonary window to the anomalous coronary ostium. The suture line starts at the anomalous coronary and is continued inferiorly along the pulmonary artery wall to the aortopulmonary window. The suture line is

completed by returning to the coronary artery and completing the superior aspect of the baffle. After the baffle is created, repair of the pulmonary artery can be accomplished using a prosthetic patch or autologous pericardium to avoid supra-valvar pulmonary artery obstruction (Fig. 124-10). The main complications of the modified Takeuchi operation include baffle leak, baffle occlusion, and supra-valvar pulmonary artery obstruction.

Postoperative Management

Regardless of the surgical technique used, the most common postoperative issues are those related to the infant's preoperative state: low cardiac output, left ventricular dysfunction, and hypotension. Optimizing the patient's hemoglobin, electrolytes, acid-base status, and fluid status and providing adequate inotropic support are extremely important. In infants and children with severe preoperative cardiac dysfunction, temporary support with an LVAD or ECMO may be necessary in

FIGURE 124-9 ■ A segment of 4-mm polytetrafluoroethylene (Gore-Tex) graft is opened longitudinally and used to fashion a baffle that directs blood flow from the aortopulmonary window to the anomalous coronary ostium. (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. In Kaiser LR, Kron IL, Spray TL, editors: *Mastery of cardiothoracic surgery*, Philadelphia, 1998, Lippincott-Raven, p 886.)

the postoperative period. Bleeding is also common postoperatively and is more frequently encountered in small infants and those who require mechanical support. Platelets and fresh-frozen plasma should be used aggressively to replace ongoing loss. Patients with low cardiac output or bleeding issues may require delayed sternal closure (2 to 3 days).

Results

Simple ligation of ALCAPA has been shown to have unacceptable early and late mortality rates. In general, survival after establishment of a dual coronary system is excellent.^{13,27} In 1987, Bunton and colleagues from Boston reported on 24 patients with ALCAPA.²⁸ From among these 24 patients, 11 received coronary ligation or ostial

closure, 11 had a Takeuchi repair, and 2 underwent other procedures. Of the patients who underwent coronary ligation or ostial closure, there was a 27% early mortality and a 25% late mortality over an average 10.5-year follow-up period. In those who underwent a Takeuchi procedure, there were no early or late deaths in over an 18.5-month follow-up period. After Takeuchi repair, two patients developed right ventricular outflow tract obstruction (one required a second operation), and one patient was found to have baffle occlusion.

Backer and colleagues reported the follow-up surgical results of 20 patients with ALCAPA who underwent different procedures.²⁹ There were two early deaths and one late death among nine patients who underwent ligation. In contrast, there were no deaths among the 10 patients who underwent creation of a dual coronary artery system

FIGURE 124-10 ■ After the baffle is completed, the pulmonary arteriotomy is repaired with a patch to avoid creation of supraventricular right ventricular outflow tract obstruction. and the one patient who had cardiac transplantation. Five patients had left subclavian-to-left coronary anastomosis, and two developed significant anastomotic stenosis.

Vouhe and associates from France reported on reimplantation of the anomalous coronary in 31 consecutive children.³⁰ Three hospital deaths and two additional deaths occurred within the first 3 months. No late deaths occurred. The only risk factor identified for early mortality was a shortening fraction of less than 20%. Twenty-three survivors were studied more than 1 year after repair. All patients had normal left ventricular function, and in five of seven patients who had severe mitral regurgitation preoperatively, the severity had decreased to mild or no regurgitation. The reimplanted coronary artery was patent in all patients.

A 2007 report by Lange and colleagues reviewed the long-term results of 56 patients with ALCAPA who underwent either subclavian artery anastomosis or coronary artery transfer.³¹ Patients who had had a Takeuchi procedure or a left mammary artery graft were excluded. There were similar early mortality rates (14%) for both surgical groups but no mortality in those undergoing repair in the last 13 years. Late mortality in each group was also similar, with one patient in each group. At final follow-up (mean 14.5 years for subclavian artery group and 8.7 years for coronary transfer group), 95% of patients had normal left ventricular function and 84%

had mitral regurgitation less than grade 2. However, if left ventricular function does not improve after revascularization, cardiac transplantation may be indicated.

Special Considerations

Mitral Regurgitation

There has been controversy regarding the management of mitral regurgitation during the initial surgery.³² In general, at least a moderate degree of mitral regurgitation is found at the initial presentation. Even in patients with severe mitral regurgitation, there have been several reports of significant improvement after coronary reperfusion alone, probably because of better left ventricular dysfunction and a decrease in left ventricular size postoperatively. Furthermore, valve repair at the time of initial surgery can result in longer ischemic times and can be technically more difficult to perform in an infant's heart than when the child is bigger. However, some authors recommend routine annuloplasty at the time of initial repair, whereas others propose annuloplasty or mitral valve replacement only with severe mitral regurgitation.³³ In summary, early surgical repair of the mitral valve is generally not necessary. If valve repair in the setting of severe mitral regurgitation is needed later, it is likely to be more successful and easier to do technically.

However, if severe mitral regurgitation persists late postoperatively, possible causes of ongoing myocardial ischemia should be investigated.

Late Presentation in the Adult

As discussed previously, ALCAPA in adults is rare, but it does occur. Surgery is indicated in all cases but is generally elective. In some adults, reimplantation can be performed. If this is not feasible, the surgical choice is coronary bypass grafting using the left internal thoracic artery in association with ligation of the proximal vessel; this is generally a low-risk procedure that all adult cardiothoracic surgeons can perform with a low mortality rate.

ANOMALOUS CORONARY ARTERY COURSE BETWEEN AORTA AND PULMONARY ARTERY

Anatomy

An anomalous course of a coronary artery between the two great vessels can result in myocardial ischemia and sudden death, notably in children and young adults. When there are two separate ostia, either the RCA or the LMCA may arise from the wrong sinus of Valsalva and subsequently course between the great vessels (Fig. 124-11). When the two ostia are in the same sinus, the ostium of the anomalous coronary artery is frequently small and slit-like with an acute-angle take-off.³⁴ A similar situation may be found if there is a single coronary artery arising from the right aortic sinus and the LMCA or LAD runs between the aorta and pulmonary artery, or if

the single coronary arises from the left aortic sinus and the RCA courses between the great vessels.³⁵⁻³⁸

Pathophysiology

When the anomalous coronary courses intramurally in the wall of the aorta between the aorta and pulmonary artery, it is associated with increased incidence of sudden death.³⁹⁻⁴⁵ The greatest danger of sudden death is during or just after maximal exertion. Both anomalous LMCA from the right sinus and RCA from the left sinus are associated with sudden death, but the former carries a higher risk. Based on autopsy studies of patients with an anomalous aortic origin of a coronary artery, sudden cardiac death is hypothesized to occur from decreased anomalous coronary blood flow resulting in myocardial ischemia or ventricular tachyarrhythmias (or both). This diminished blood flow is probably the result of an anatomic malformation of the anomalous vessel. The risk of ischemia is greatest with vigorous exercise, when there is a significantly greater cardiac output and oxygen demand placed on the heart.⁴⁶⁻⁴⁸

Clinical Presentation

The true prevalence of an anomalously coursing left or right coronary artery between the aorta and pulmonary artery is unknown, but estimates range from 0.1% to 0.3% of the general population.^{49,50} What makes this diagnosis especially challenging is that there are no characteristic physical findings in these patients, and the physical examination is almost always normal. In children, an innocent murmur may be auscultated, which prompts the referral to a cardiologist, who may perform an echocardiogram. Many patients with this anomaly are asymptomatic, and the initial presentation may be sudden death.⁴⁷⁻⁴⁹ When symptoms are present, they most commonly include chest pain, palpitations, dizziness, pre-syncope, or syncope during or just after exertion.^{42,51-54} The diagnosis must be considered in any young patient with exercise-induced complaints suggestive of myocardial ischemia or in those who experience aborted sudden death or sudden death.⁵⁵ Screening first-degree relatives with echocardiography has recently been suggested because of a potential genetic link with this anomaly.⁵²

Diagnostic Imaging

Anyone with pre-syncope, syncope, or chest pain during or just after exertion deserves attention and further evaluation. A resting ECG should be obtained to evaluate for ventricular hypertrophy, arrhythmias, and evidence of previous myocardial infarction.

Echocardiography with color Doppler should be performed to ensure normal intracardiac anatomy and to evaluate heart function, especially focusing on areas of abnormal wall motion signifying possible history of ischemia.^{52,53,56} The proximal coronary anatomy should be evaluated with close attention paid to the coronary artery origins. Improvements in two-dimensional echocardiography have made the identification of the origins of both coronary arteries possible in many patients, especially

FIGURE 124-11 ■ **A**, Anomalous origin of the right coronary artery from the left aortic sinus with abnormal coursing of the right coronary artery between the aorta and pulmonary artery. **B**, Abnormal origin of the left main coronary artery from the right aortic sinus with abnormal coursing of the left main coronary artery between the aorta and pulmonary artery. (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. In Kaiser LR, Kron IL, Spray TL, editors: *Mastery of cardiothoracic surgery*, Philadelphia, 1998, Lippincott-Raven, p 890.)

when combined with color flow Doppler mapping to identify the anomalous origin. This technique may be necessary because in patients in whom the anomalous vessel courses intramurally within the aortic wall, when two-dimensional imaging is used alone, the anomalous vessel may appear to arise normally where it exits the aorta. Color Doppler imaging can demonstrate the abnormal direction of blood flow within the aortic wall, helping to delineate an anomalous vessel from one that arises normally.

Other noninvasive techniques, such as MRI or CT, may be used when the coronary artery origins cannot be adequately delineated, or to confirm the diagnosis.^{57,58} Occasionally, cardiac catheterization with angiography or transesophageal echocardiography is used to visualize the coronary anatomy; however, these more invasive options are not the first choice in children, although they may be used more often in adults. Indeed, although cardiac catheterization with coronary angiography still remains the gold standard for detecting anomalous coronary arteries, it is being replaced by noninvasive imaging. Coronary angiography may be necessary in adult patients to evaluate for other coronary disease before undergoing surgical intervention.⁵⁹

Most patients undergo further evaluation for myocardial ischemia at rest and stress. This usually includes an exercise stress test with some form of imaging study, such as a nuclear perfusion study or stress echocardiography. However, basing management decisions on a single exercise test may not be reliable, because ischemia is intermittent in patients with an anomalous aortic origin of a coronary artery, so a single test may be normal.⁶⁰ In a study performed at our institution evaluating children with anomalous aortic origin of a coronary artery, 9 of 16 who had a preoperative exercise test had presented with cardiovascular symptoms, but only 1 had an abnormal exercise test.⁵¹ Furthermore, normal exercise tests have been reported in patients who experienced sudden death after the test was performed.

Surgical Management

Indications for Surgery

Surgical intervention is indicated in any patient with anomalous aortic origin of a coronary artery with an interarterial course who has signs or symptoms of myocardial ischemia or ventricular arrhythmias. Furthermore, most would agree that surgery is indicated in asymptomatic patients with anomalous left coronary artery because of the high risk of sudden death. The management of asymptomatic patients with anomalous RCA has not been defined, and the controversy is even greater when treating children and young adults, who appear to have a higher risk of sudden death than those identified later in adulthood.

Surgical Techniques

Unroofing Procedure. The unroofing procedure has become the procedure of choice for patients with anomalous coronary artery with an interarterial and intramural

FIGURE 124-12 ■ When the coronary artery arises anomalously from the opposite sinus of Valsalva and courses between the pulmonary artery and the aorta, the ostium is frequently abnormal. Repair may be undertaken by remodeling the ostium. The abnormal ostium is usually located near a commissure, and this commissure must be initially taken down to allow remodeling of the ostium. (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. In Kaiser LR, Kron IL, Spray TL, editors: *Mastery of cardiothoracic surgery*, Philadelphia, 1998, Lippincott-Raven, p 891.)

course.^{51,53,61,62} After the median sternotomy is performed, the pericardium is opened and the anatomy is inspected. Cannulation of the aorta occurs close to the innominate artery, and a two-stage venous cannula is inserted via the right atrial appendage. After cardiopulmonary bypass is established with moderate hypothermia, a left ventricular vent is placed via the right superior pulmonary vein. A cannula is placed in the ascending aorta for administration of cardioplegia solution. The aorta is cross-clamped and cardioplegia solution is administered. A transverse aortotomy is performed after adequate arrest is achieved and the coronary ostia are identified. If the anomalous coronary ostium arises close to the aortic valve commissure, it may be necessary to take down the commissure (Fig. 124-12). To enlarge the often slit-like ostium, it is opened longitudinally starting at the anomalous coronary os and continuing into the correct sinus (Fig. 124-13). A segment of the common wall between the aorta and the coronary is excised, and the intimal surfaces are approximated with interrupted sutures using 8-0 Prolene. If necessary, the aortic valve commissure is resuspended with a pledgeted suture (Fig. 124-14). The aortotomy is then repaired, and the cross-clamp is removed after de-airing. As the patient is rewarmed, close attention should be paid to the ECG to evaluate for signs of myocardial ischemia. The patient is then separated from cardiopulmonary bypass in the usual fashion.

Creation of a Neo-Ostium. An alternative technique that may be used when the anomalous coronary passes intramurally below the aortic valve commissure is the creation of a neo-ostium in the correct sinus. A probe is passed through the intramural segment of the anomalous coronary into the correct sinus. The coronary artery is

FIGURE 124-13 ■ After the commissure is detached, the abnormal coronary is incised longitudinally, beginning at the abnormal ostium, and this incision is carried into the right aortic sinus. A portion of the common wall between the aorta and coronary is excised. (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. In Kaiser LR, Kron IL, Spray TL, editors: *Mastery of cardiothoracic surgery*, Philadelphia, 1998, Lippincott-Raven, p 892.)

FIGURE 124-14 ■ The walls of the coronary artery and aorta are anastomosed with interrupted sutures of 8-0 polypropylene (Prolene), enlarging the ostium and preventing compression by the great vessels. The commissure of the aortic valve is resuspended with a pledgeted suture. (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. In Kaiser LR, Kron IL, Spray TL, editors: *Mastery of cardiothoracic surgery*, Philadelphia, 1998, Lippincott-Raven, p 892.)

opened at the location where it exits the aorta, and a neo-ostium is created. The intima is sewn to the aortic wall with interrupted sutures. This technique avoids the take-down and resuspension of the commissure.

Other Techniques. When there are two separate coronary ostia with an interarterial but not an intramural course, coronary artery translocation with reimplantation has been advocated.⁶² This is similar to reimplantation

done for the arterial switch procedure as described earlier for the ALCAPA repair. The coronary artery is excised with a button of aortic tissue and usually reimplanted above the commissure in the correct sinus. It has been suggested that compression of the coronary artery between the aorta and the pulmonary artery can be prevented by translocating the MPA to the left pulmonary artery, or by translocating the right pulmonary artery and bifurcation anterior to the aorta, thereby leaving the coronary circulation intact.⁶³ This technique may be used when the anomalous coronary course is not intramural but the ostia are close together. Combining coronary artery patch angioplasty using pericardium in addition to translocating the MPA to the left pulmonary artery has also recently been proposed.⁶⁴ Coronary artery bypass grafting using saphenous vein or IMA grafts may be appropriate in the older adult; however, concern about long-term graft patency in the young patient makes this a less desirable surgical option in children and young adults.

Surgical Results

No data exist regarding long-term neo-ostia patency rates after the unroofing procedure. Short- to mid-term results overall have been reassuring, with no reports of ostial stenosis by echocardiography. However, in a study by Romp and colleagues, one patient developed severe aortic insufficiency requiring aortic valve replacement 44 months after the initial operation.⁵⁴ At our institution in a study by Brothens and colleagues that evaluated children in the short to mid term after unroofing, subclinical evidence of postoperative myocardial ischemia was found in half of the patients with anomalous RCA and in one of eight patients with anomalous left coronary artery.⁵¹ This was despite patent neo-coronary ostia by echocardiography and with the patients remaining asymptomatic during testing. A follow-up study by Wittlieb-Weber and colleagues evaluating these same patients in the intermediate term after unroofing procedure found almost half (46%) of the 24 children experienced perioperative pericardial effusions and 4 (16%) developed mild aortic insufficiency.⁶⁵ The clinical implications of these findings in the long term are unknown, and further evaluations are needed over the next several years.

Although coronary artery reimplantation has been used by some, one study by Rinaldi and colleagues reported that two patients required emergency bypass grafting.⁶⁶ In an analogous procedure used for transposition of the great arteries, long-term follow-up studies demonstrated coronary obstruction in up to 8% of patients, with Pedra and associates noting proximal eccentric intimal thickening by intravascular ultrasound in most patients evaluated at least 5 years after the original surgery.⁶⁷ The long-term success of pulmonary artery translocation procedures is not known.

CORONARY ARTERY FISTULA

A coronary artery fistula is an abnormal communication between a coronary artery and a cardiac chamber or any of the great vessels (coronary sinus, venae cavae, pulmonary artery, or a pulmonary vein).^{68,69} Coronary

arteriovenous fistulas are those that end in right-sided structures, such as the right atrium, right ventricle, or pulmonary artery, whereas those that terminate in left-sided structures are called arterio-arterial fistulas.

Coronary artery fistulas are usually congenital, comprising 0.2% to 0.4% of congenital heart defects, but they make up almost half of all congenital coronary anomalies. They can be found in isolation or in association with other congenital heart disease. Acquired fistulas are the result of cardiac surgery, cardiac catheterization, or a complication from Kawasaki disease.⁷⁰

Anatomy

Coronary artery fistulas may arise from either the right or the left coronary artery; occasionally, both coronary arteries are affected.⁷¹ Most fistulas arise from a coronary artery with an otherwise normal distribution. The fistulous connection may occur in the midportion of the coronary artery with a normal vessel continuing beyond the fistula origin, or as an end artery at the termination of the vessel. The coronary is dilated and elongated in the portion of the vessel proximal to the fistula, usually in proportion to the size of the shunt across the fistulous connection. The portion of the vessel distal to the fistula usually returns to a small diameter.

The right ventricle and right atrium are the most common sites of termination. Fernandes and colleagues reported on 93 patients with coronary artery fistulas.⁷² A single fistula was present in 83 patients, and the other 10 had multiple fistulas. The RCA was the most common site of origin and the right ventricle was the most common drainage site. Fifty-six patients had isolated coronary fistulas, and the others had additional cardiac lesions. Lowe and colleagues reviewed 286 patients and found the RCA to be the site of origin in just over half of the patients, and the left coronary artery system the origin site in approximately one third.⁷³ The right ventricle was the most common site of drainage (39%), with the right atrium (including the coronary sinus and superior vena cava) and the pulmonary artery as the drainage sites in 33% and 20%, respectively. The site of drainage was the left atrium or left ventricle in the remaining 8%.

Pathophysiology

Coronary fistulas result in a left-to-right or left-to-left shunt. When a fistula drains to the right side of the circulation, there is usually a small- to moderate-sized shunt. However, when it drains into a left-sided chamber (i.e., left-to-left shunt), an aortic runoff develops, with physiology similar to that of aortic regurgitation. The effects of the shunt are related to the amount of blood flow from the fistula to the chamber and into which chamber the fistula drains. It can also be affected by myocardial ischemia resulting from coronary circulation steal.

Clinical Presentation

Patients with a coronary artery fistula are usually asymptomatic; they rarely present in infancy and are often diagnosed in adulthood. Many patients are diagnosed during a murmur evaluation. When symptomatic, the most

common complaints are shortness of breath with exercise and fatigue. Even though there may be coronary steal, angina is uncommon. Ventricular dysfunction and congestive heart failure are occasionally present and are much more common in the adult. Atrial fibrillation in an older patient may result from right atrial enlargement caused by a coronary artery fistula to the right atrium.

On examination of a patient with a coronary artery fistula, a continuous murmur is often auscultated. The murmur may be suggestive of a PDA, but it is heard lower on the sternal border, which is an atypical location for a PDA. As is the case with aortic regurgitation, large left-to-left shunts may cause a wide pulse pressure.

Natural History

In patients with congenital coronary arterial fistulas, most likely the fistula was present early in life and gradually increased in size over several years. Despite progressive enlargement of the coronary arteries, spontaneous rupture is rare and usually results from aneurysmal dilation and weakening of the vessel wall as a result of a congenital defect or atherosclerosis. Bacterial endocarditis can occur secondary to turbulent flow. Spontaneous closure of small fistulas has been reported.

Diagnostic Imaging

Depending on the size of the fistula, the ECG may be normal, or it may show evidence of ventricular volume overload. Atrial fibrillation may be noted in older adult patients who have a right atrial fistulous connection. If coronary steal is present, evidence of myocardial ischemia in the affected region may be noted. Chest films are usually normal but may show cardiomegaly or evidence of congestive heart failure. Giant aneurysms of the involved coronary artery can sometimes be noted. Two-dimensional echocardiography can demonstrate the enlarged coronary artery, the origin of the fistula, the chamber into which it drains, and any cardiac chamber enlargement or hypertrophy. The actual fistula may be demonstrated best by color Doppler. MRI is a promising additional noninvasive imaging technique used to diagnose and provide detailed anatomy of the coronary arterial fistula and may take the place of cardiac catheterization, but now it is used as an adjunctive imaging modality.

Coronary catheterization with selective coronary angiography remains the gold standard to accurately define the coronary anatomy and the hemodynamic significance of the fistula. Often, an experienced interventional cardiologist can successfully coil-embolize the coronary artery fistula without the morbidities associated with cardiopulmonary bypass and sternotomy.⁷⁴ However, the indications for coil embolization have not been defined; therefore, most patients undergo surgical closure as the preferred therapy.⁷⁵

Surgical Management

Indications for Surgery

All patients with symptomatic fistulas should undergo closure. Patients with very small fistulas may not require

FIGURE 124-15 ■ If the termination site of the fistula is at the distal aspect of the coronary and no significant myocardium is in jeopardy, the coronary may be ligated proximal to the termination site. If the fistula terminates in the midportion of the left anterior descending coronary artery, the fistulous communication may be closed with multiple pledgeted sutures placed underneath the coronary artery so as not to impair distal perfusion. (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. In Kaiser LR, Kron IL, Spray TL, editors: *Mastery of cardiothoracic surgery*, Philadelphia, 1998, Lippincott-Raven, p 888.)

surgical closure; however, because the natural progression of a fistula is to enlarge, these patients should be closely followed.⁷⁶ Asymptomatic patients with moderate to large fistulas should undergo surgical closure electively.

Surgical Techniques

Coronary artery anatomy must be clearly defined by coronary angiography before surgical closure. Each operation should be individualized on the basis of anatomy. Often, the fistula can be ligated or oversewn at its origin or termination without the use of cardiopulmonary bypass; however, cardiopulmonary bypass should always be available.

Through a median sternotomy, the coronary anatomy is visualized and carefully inspected, and the site of the enlarged vessel is noted. The fistula can be ligated without the use of cardiopulmonary bypass when it is located at the distal end of the coronary artery and there is no viable myocardium distal to the fistula (Fig. 124-15). This is performed by placing a ligature around the coronary artery immediately proximal to the fistula, thereby temporarily occluding the fistula. The heart is observed for signs of ischemia, and the ECG is monitored closely. If there are no signs of ischemia and there is adequate myocardial perfusion, the ligature is tied. To ensure complete closure, a second suture ligature should also be placed. Intraoperative transesophageal echocardiography can be used to verify that the fistula is closed.

Cardiopulmonary bypass is indicated if the fistula arises from the middle of a coronary artery, if the fistula is inaccessible, if another cardiac lesion needs to be repaired simultaneously, or if the complete coronary course cannot be completely defined. The aorta and both cavae are cannulated and bypass is initiated. If cardioplegic arrest is necessary, the fistula should be temporarily compressed during administration of the cardioplegia to prevent runoff through the fistula into the heart. If adequate arrest is not possible because of flow through the fistula, retrograde administration of cardioplegia solution may be necessary.

A variety of techniques can be used to close the fistula. If it ends in the midportion of the LAD, the fistulous communication can be closed by placing multiple pledgeted sutures beneath the coronary artery, taking care to avoid compromising distal perfusion (see Fig. 124-15). However, if distal perfusion of the coronary bed is affected after closure of the fistula, coronary bypass grafting may be necessary. Another technique that can be used when the fistula arises from the midportion of the coronary is to open the coronary longitudinally on the epicardial surface and oversee the origin of the fistula from within the coronary artery (Fig. 124-16). The coronary artery can then be closed primarily.

If the fistula terminates in the right atrium or right ventricle, the fistula may be closed directly from within the cardiac chamber (Fig. 124-17). A right atriotomy is performed after cardiopulmonary bypass, and the termination site of the fistula is identified from within the

FIGURE 124-16 ■ **A**, When the fistulous communication arises from the midportion of the dilated coronary, the coronary may be opened longitudinally and the origin of the fistula oversewn from within the coronary. **B**, The coronary artery is closed primarily. chamber. Using cardioplegia may be helpful for localization. The termination site can be closed primarily or with a pericardial patch (Fig. 124-18).

Surgical Results

The operative mortality rate for coronary artery fistula repair is very low, and late results are outstanding with very few patients experiencing a recurrence of the fistula.^{71,77} Lowe and colleagues reported on 22 patients after surgical closure of coronary artery fistulas.⁷³ In 14 patients, the fistula was closed using sutures without cardiopulmonary bypass. The termination of a fistula within a cardiac chamber was closed using cardiopulmonary bypass in six patients. In the remaining two patients, saphenous vein bypass grafts were necessary to maintain distal perfusion after fistula closure. The operative mortality rate was zero, as was the long-term rate at an average follow-up of 10 years. Although a small residual fistula remained in one patient, there were no recurrences. Fernandes and colleagues reported on 56 patients who had coronary artery fistula closure.⁷² There was no early or late mortality, but two patients had perioperative myocardial infarctions. Finally, Mavroudis and colleagues reported on 17 pediatric patients with an average age of 5.5 years.⁷⁵ Eight underwent fistula closure using cardiopulmonary bypass, and one of these patients needed distal IMA bypass graft. There was complete closure in all patients, and there were no recurrences and no operative or late deaths.

FIGURE 124-18 ■ After institution of cardiopulmonary bypass and induction of cardioplegia, the right atrium is opened, and the termination site of the fistula is identified from within the right atrium. This may be done primarily or with a patch of pericardium. (Reprinted with permission from Gaynor JW: Coronary artery anomalies in children. CONGENITAL OSTIAL ATRESIA OF THE LEFT MAIN CORONARY ARTERY

Anatomy

Congenital atresia of the LMCA ostium is a congenital coronary anomaly that is quite rare, with fewer than 50 reported cases in the literature. In this coronary anomaly, there is no LMCA ostium; rather, the correctly positioned LAD and circumflex coronary arteries have a blind ending and they receive blood flow retrograde through the RCA via at least one collateral vessel.⁷⁸ On the inner aortic surface in the left sinus of Valsalva, there may be a dimple, a blind pouch, or no marking at all. This lesion should be differentiated from a single RCA where blood flow occurs in a centrifugal, or antegrade, manner. Most patients with a single RCA remain asymptomatic, except in the setting of atherosclerosis or other congenital heart defects. The congenital atresia of the LMCA ostium usually occurs in the absence of other structural heart disease; however, associations have been noted with supralvalvar aortic stenosis, VSD with pulmonic stenosis, right coronary ostial stenosis, and PDA and aortic regurgitation.^{78,79}

Pathophysiology

The main pathophysiology from congenital left main ostial atresia is inadequate collateral vessel flow from the RCA. Blood flows from the RCA to the left coronary artery system through collateral vessels, which are smaller in size than the left-sided coronary arteries; thus, there is inadequate blood flow through these smaller vessels to

perfuse the myocardium. This leads to myocardial ischemia and the potential for sudden death and causes these patients to be almost universally symptomatic.

Clinical Presentation

The timing of when these patients present with symptoms can occur at different ages, with some presenting during infancy and others in adolescence or adulthood. Despite age at presentation, almost every patient reported in the literature was symptomatic at diagnosis, although the signs and symptoms were different. The infants and toddlers generally present with heart failure symptoms, including feeding difficulty, failure to thrive, emesis, and dyspnea.^{78,80} Their clinical picture is similar to that of ALCAPA or dilated cardiomyopathy, both of which would need to be ruled out as well. The youngest patients also are more likely to have an associated cardiac defect, suggesting that there are earlier ischemic events from other congenital lesions that may increase the myocardial oxygen demand. School-age children and adolescents may be diagnosed after experiencing syncope, dyspnea, angina, and ventricular tachyarrhythmias, whereas adults are likely to have dyspnea and angina. Indeed, for any age, sudden death may be the first presentation.

Diagnostic Imaging

Accurate diagnostic imaging is essential in this diagnosis because symptoms are nonspecific and can be caused by other diseases. In young children, cardiomegaly with pulmonary congestion as a result of heart failure may be evident on chest radiograph, whereas in adults, the radiograph may be normal. The 12-lead ECG may be normal or may show a variety of abnormalities, including anterolateral Q waves, lateral T wave inversion, right bundle branch block, or ventricular tachycardia. The initial imaging procedure should be transthoracic echocardiography. This is likely to show a dilated left ventricle with poor function and mitral regurgitation, a finding also seen with ALCAPA and dilated cardiomyopathy. Delineation of the coronary artery ostia is essential. The use of Doppler color flow is helpful to demonstrate flow from the RCA retrograde to the left coronary artery system without evidence of blood flowing to the pulmonary artery. Although echocardiographic techniques have improved over the past several years, delineating coronary anatomy and blood flow can be difficult in some cases. Because of this, cardiac catheterization with coronary angiography remains the gold standard and should be performed on any patient who may have either ALCAPA or congenital atresia of the left main coronary ostium. The direction of flow from the RCA to the left coronary system and whether the PA is filled retrograde should be delineated. If any question remains regarding the diagnosis, selective RCA angiography should be performed.

Surgical Management

Once diagnosed, surgery should occur expeditiously because of the high risk of sudden death with this anomaly.

FIGURE 124-19 ■ Technique for ostioplasty of the left coronary ostium with homograft patch. Left coronary ostial atresia before intervention (*main illustration*) and with homograft patch augmentation of the ostium and left main coronary artery (*inset*). (Reprinted with permission from Kaczorowski DJ, Sathanandam S, Ravishankar C, et al: Coronary ostioplasty for congenital atresia of the left main coronary artery ostium. *Ann Thorac Surg* 94:1307–1310, 2012, Fig. 2.)

The literature mainly reports the use of coronary artery bypass grafting (CABG) for all ages.^{78,81,82} Some reports have described the creation of a dual coronary artery system for these patients, with the belief that, similar to ALCAPA, long-term outcomes may be improved.^{80,83,84} This type of surgical revascularization has important implications for children and young adults in whom the bypass graft longevity is of concern.

For the creation of a dual coronary artery system, there have been a few somewhat different surgical techniques described. Varghese and colleagues described the use of an autologous pericardial patch to attain surgical revascularization in a single case of left main coronary ostial atresia.⁸³ The aorta is transected under cardiopulmonary bypass to find the dimple from where the left coronary normally would be located. An incision is made vertically in the aorta to the location of the ostium and then extended down the LMCA; the incision should end prior to the LAD and circumflex coronary artery bifurcation. An atretic membrane, if present, should be removed. An autologous pericardial patch is then used to reconstruct the LMCA ostium that is atretic.

Bonnet and colleagues described surgical revascularization of the left main coronary arteries and included two of the patients with LMCA atresia.⁸⁴ To help attain myocardial preservation, after standard cardiopulmonary bypass, first hot-induction blood cardioplegia, followed by cold blood cardioplegia, and subsequent warm reperfusion are used. The MPA is then transected so that the aortic root and left coronary artery system can be visualized. The aortic incision starts on the anterior portion of the aortic root, continues toward the coronary orifice, and extends beyond the atretic portion. The aortic and coronary incisions are then connected together using an onlay patch, which is obtained from saphenous vein,

autologous pericardium, or PTFE. The creation of this patch enlarges not only the LMCA but also the section of the aorta that was incised, now creating a “funnel-shaped” neo-ostium.

A third revascularization procedure, as described by Kaczorowski and colleagues, is homograft patch ostioplasty in the treatment of LMCA ostial atresia (Fig. 124-19).⁸⁰ Bicaval cannulation is used and cardiopulmonary bypass established. Two of the three children in the report were initially diagnosed with ALCAPA; therefore, their pulmonary artery was opened to evaluate for a coronary ostium. When there was not one identified, an aortotomy was performed. No left main coronary ostium was identified in the aorta. After the blind-ending LMCA was located on the cardiac surface, in two patients, an incision was made in the aortic wall that was directed inferiorly to the aortic sinus. A second incision was made in the LMCA until its division into LAD and circumflex coronary arteries. Using a pulmonary homograft patch, the ostium was enlarged and also joined the aortic sinus to the proximal LMCA. In the third patient, the blind-ending LMCA was sewn onto the posterior aortic wall with anterior augmentation. To help confirm coronary patency, coronary probes should be used as well as noting evidence of back bleeding. The aortotomy is subsequently closed and the patient is removed from bypass.

Surgical Results

Postoperative morbidity and mortality, at least in the short-term, appear to be related to amount of myocardial damage at the time of diagnosis and operation. If LMCA ostial atresia is recognized early and the patient has enough collateral vessels, then short-term results are encouraging after surgical revascularization, notably with

those procedures that establish a dual coronary system. However, long-term outcome data are lacking in this population. Long-term results from CABG used for other coronary arterial abnormalities (e.g., ALCAPA) remain somewhat uncertain, although some reports using IMA grafts have shown good results.

OUTCOMES

Surgical outcomes after repair of anomalous coronary artery arising from the pulmonary arteries have significantly improved over the past several years, even in the high-risk patients who present with significant left ventricular dysfunction and mitral regurgitation. Overall survival is now greater than 90%. Mitral valve repair is rarely needed, even in patients with severe preoperative mitral regurgitation. Long-term outcome data are limited, particularly with regard to left ventricular function and late mortality. The data suggest that establishing a dual coronary system is associated with overall improved survival and left ventricular function when compared with simple ligation of the anomalous artery.⁸⁵

Similarly, there are limited data on long-term morbidity and mortality after surgical repair of anomalous aortic origin of a coronary artery coursing between the aorta and the pulmonary artery.^{13,60,65,86} Surgical mortality appears to be rare. It is unknown whether these surgical techniques truly reduce the incidence of myocardial ischemia and sudden cardiac death. After surgical closure of coronary artery fistulae, mortality is minimal with a low recurrence rate and excellent long-term outcome.^{72,75} No long-term data are currently available for operative mortality after LMCA ostial atresia repair. Short-term results are encouraging when there is early recognition of the anomaly, the patient has adequate collateral vessels, and surgical revascularization consists of establishing a dual coronary artery system.^{80,83,84}

SUMMARY

HISTORY

Transposition of the great arteries (TGA) was first recognized and described more than 2 centuries ago. Although reference was made to malposition of the aorta and pulmonary artery by Steno in 1672 and Morgagni in 1761, the anatomic description of TGA is credited to Baillie in 1797.¹ It was Farre in 1814 who introduced the term *transposition of aorta and pulmonary artery*, meaning that the aorta and pulmonary artery are displaced across

the ventricular septum.² An attempt to classify the various types of transposition was reported by von Rokitsansky, and the first clinical recognition of TGA in life was noted by Fanconi in 1932.^{3,4} In 1938, Taussig described the pathologic anatomy and hemodynamic and clinical characteristics of the cardiac defect.⁵

With the development of cardiac surgery in the 1950s, effective therapy for this disease is relatively new. Initial treatments were palliative and included atrial septectomy, first described by Blalock and Hanlon.⁶ The first successful attempts to reroute the circulations were at the atrial

level. These attempts were followed later by successful arterial level repair and correction of TGA and ventricular septal defect (VSD). These developments are further described in this chapter.

EPIDEMIOLOGY

Today TGA is known to be relatively common, accounting for 9.9% of infants with congenital heart disease, or 0.206 of 1000 live births, in one New England study.⁷ The 2:1 male-to-female ratio increases to 3.3:1 when the ventricular septum is intact.⁸ In complex forms of transposition, gender predominance has not been noted. If TGA is not treated, 90% of children with D-TGA (see [Classification and Embryology](#) section for explanation of D-TGA) and intact septum will die by 1 year of age.

CLASSIFICATION AND EMBRYOLOGY

TGA is generally classified as a type of conotruncal abnormality, a group of abnormalities that has a common theme of deranged development of the cardiac outflow tract. In this disease, there is ventriculoarterial discordance—the aorta arises from the right ventricle and the pulmonary artery from the left ventricle. The more common form of the disease is associated with otherwise normal cardiac structural relationships, including normal ventricular (D) looping. There is atrioventricular concordance but ventriculoarterial discordance {S,D,D}. This set of relationships is commonly referred to as D-transposition (D-TGA). In this form of TGA, the aorta is, by definition, anterior and to the right of the pulmonary artery. This pattern results in the systemic and pulmonary circulations performing in parallel rather than in series. As a consequence, deoxygenated blood is continuously pumped to the body and never passes through the lungs, and oxygenated blood is recirculated through the lungs and does not supply the rest of the body. For the patient to survive, there must be an obligatory shunt elsewhere, usually at the level of the atrial septum, that allows mixing of oxygenated and deoxygenated blood.

Although some have used the term *transposition* to describe a discordant ventriculoarterial connection, other authors have used this term to describe any heart in which the aorta is anterior to the pulmonary artery. The term *TGA* has also been used to describe some patients with double-inlet ventricle or absent atrioventricular connection and patients with nonlateralized atrial arrangements (some heterotaxy syndromes). *D-TGA* has been used to describe a concordant atrioventricular and discordant ventriculoarterial arrangement, but this nomenclature does not adequately describe patients in whom the aorta is anterior and to the left of the pulmonary artery. Thus, in this chapter, complete TGA is defined as normal atrial situs, atrioventricular concordance, and ventriculoarterial discordance.

Several theories have been advanced regarding the morphogenesis of the abnormal relationship between the great arteries and the ventricles in patients with TGA. It has been suggested that the subaortic conus persists and

develops during normal looping of the ventricles while the subpulmonary conus undergoes absorption and thus establishes eventual fibrous continuity between the mitral and pulmonary valves, the reverse of the normal situation.⁹ In the normal heart, the subaortic conus does not grow, and dominant growth of the pulmonary conus forces the pulmonary valve anterior, superior, and to the left. In transposition, differential growth of the subaortic conus pushes the aorta anteriorly and disrupts aortic to mitral valve continuity. If the subpulmonary conus fails to develop, the pulmonary artery will maintain a posterior location and pulmonary to mitral valve continuity will occur. As a consequence of this relationship, the aortic valve becomes anterior to the pulmonary valve, permitting both semilunar valves to connect with the distal great vessels without the rotation that is hypothesized to occur in normal cardiac development. Because conal development determines rotation of the truncus arteriosus, the great arteries are similar in relationship at the semilunar valves as they are at the arch, resulting in no twist in the great arteries.

Some debate also exists about the relationship between the various conotruncal abnormalities, which include tetralogy of Fallot and double-outlet right ventricle. Recent evidence suggests that TGA may be unique in that it is not seen in the spectrum of conotruncal abnormalities generated from the most common experimental model of these disorders.¹⁰ A new animal model, which is the most reliable to date for producing isolated D-TGA, suggests that TGA may be the result of abnormal migration of neural crest cells during a critical phase of outflow tract development.¹¹

ANATOMY

Anatomic variations in TGA can increase the surgical complexity of repair, described later in this chapter. Normal atrial situs occurs in 95% of patients, whereas left-to-right juxtaposition of the atrial appendages signals the presence of other intracardiac anomalies. Although a true ostium secundum atrial septal defect (ASD) is present in 10% to 20% of cases, most atrial communications are through a patent foramen ovale. Right aortic arch is present in 4% of patients with intact ventricular septum and up to 16% of those with VSD.¹² Up to 50% of patients with TGA have an associated VSD, many of which spontaneously close.¹³ The VSDs are commonly perimembranous, although they may be found anywhere in the ventricular septum. Pulmonary stenosis or atresia, overriding or straddling atrioventricular valves, coarctation of the aorta, and interruption of the aortic arch have all been noted in association with transposition and VSD.

The spatial relationship of the great vessels is variable; however, the aorta is most frequently to the right and anterior to the pulmonary artery. In almost all cases, the sinuses of Valsalva and the coronary artery ostia face the corresponding pulmonary arterial sinuses. This situation is favorable for transfer of the coronary arteries with the arterial switch operation, although the origin of a coronary artery from a nonfacing sinus poses a problem for arterial switch in only a small number of patients. Many

FIGURE 125-1 ■ The six most common types of coronary artery anatomy in transposition of the great arteries (TGA). Descriptive classification is on the left, and three simplified classification codes are on the right. CCA, Circumflex coronary artery; LAD, left anterior descending artery; RCA, right coronary artery.

classification systems have been used to describe the coronary anatomy in TGA. The most widely accepted scheme within the surgical community is the Leiden classification system, which is depicted with the other common systems of classification in Figure 125-1. The most common coronary pattern in D-TGA (68%) consists of the left main coronary arising from the leftward coronary sinus, giving rise to the left anterior descending and circumflex coronary arteries.¹⁴ The right coronary artery arises as a separate ostium from the rightward

posterior-facing sinus. Occasionally, there is no true circumflex coronary artery, but separate branches arise from the left coronary to supply the corresponding portion of the left ventricle. In up to 20% of cases, the circumflex coronary arises from the right coronary artery off the rightward posterior-facing sinus and passes behind the pulmonary artery. The left anterior descending artery then arises from a separate coronary ostium off the left coronary sinus. More rare coronary patterns involve a single right coronary artery from the rightward posterior sinus (4.5%) or a single left coronary artery from the leftward coronary sinus (1.5%).¹⁵ Intramural coronary arteries that proceed in the aortic wall for a distance before exiting to the epicardial surface have been described and commonly occur at the commissural attachment of the semilunar valve.¹⁶ A single coronary ostium or separate ostia close together arising from a single sinus have also been described. Abnormal coronary anatomy is more commonly seen in transposition with VSD than in the intact septum variety. Abnormal coronary patterns have also been found to be more common when the relationship of the great arterial trunks is not usual (aorta anterior and to the right).¹⁷

CLINICAL FEATURES

In complete TGA, the pulmonary and systemic circulations exist in parallel instead of in series. This results in nonoxygenated venous blood passing through the right ventricle to the aorta while the oxygenated pulmonary venous blood passes through the left ventricle back to the pulmonary arterial circulation. Mixing between the pulmonary and systemic circulations through a patent foramen ovale or ASD, a VSD, or a patent ductus arteriosus (PDA) is mandatory for survival. Patients with TGA and an intact ventricular septum survive initially because of aortopulmonary flow through a PDA. After birth, both ventricles are relatively noncompliant, and infants with TGA often have an increased pulmonary blood flow, which causes enlargement of the left atrium and functional incompetence of the foramen ovale, resulting in atrial-level mixing of oxygenated and nonoxygenated blood. Inadequacy of this mixing, however, may result in only marginal tissue oxygenation, which does not improve with oxygen administration.

Patients with TGA and significant VSD often have higher oxygen saturations by virtue of greater pulmonary blood flow and greater mixing at both atrial and ventricular levels. In children with high pulmonary blood flow, pulmonary resistance may progressively increase throughout infancy. Ferencz has observed significant histologic changes in children older than 2 years of age with TGA, and children as young as 1 month of age have had intimal fibrosis noted in the pulmonary arteries.¹⁸ This early development of severe pulmonary vascular disease in children with TGA is exacerbated in patients with associated VSD, but early important pulmonary vascular disease can occur in patients with TGA regardless of the presence of a VSD as demonstrated by Ferguson in 1960 and Ferencz in 1966.^{18,19} The rapidity of development of pulmonary obstructive disease may be related to

FIGURE 125-2 ■ The normal left ventricular (LV) wall thickness in transposition of the great arteries (TGA) after birth. The *solid line* shows the decreased development of LV mass in TGA that results from a rapid decrease in pulmonary vascular resistance and drop in LV pressure. The *upper bar* shows an increase in LV thickness with normally related great arteries. The *dashed line* shows the similar increase in right ventricular (RV) muscle mass over time in TGA. CL, Confidence limits; IVS, intact ventricular septum.

hypoxemia associated with increased sympathetic activity and in association with excessive pulmonary blood flow.²⁰

Although neonatal pulmonary vascular resistance is normal in infants with TGA, the resistance falls progressively during the neonatal period with associated changes in the pulmonary and systemic ventricular compliance. Shortly after birth in the normal infant, there is an increase in the left ventricular volume load and pressure load and a decrease in right ventricular volume and pressure load. These physiologic changes result in a rapid increase in the left ventricular myocardial mass.²¹ This normal development of the left ventricle is lost in infants with D-TGA where the left ventricle ejects to the lower resistance pulmonary vascular bed (Fig. 125-2). Thus, the left ventricle does not increase muscle mass relative to the right ventricle, and within a few weeks it loses the ability to maintain adequate cardiac output against significant afterload. This change occurs despite the fact that the left ventricle still maintains a volume load in patients with transposition and an intact ventricular septum. When, however, a VSD or large PDA is present, both volume and pressure overload of the left ventricle is maintained, and in D-TGA with left ventricular outflow tract (LVOT) obstruction without a VSD, a ventricular pressure load is imposed without a significant volume load. These physiologic changes in the neonatal heart are important for the consideration of surgical approaches

because after a few weeks to months of postuterine life, the left ventricle in D-TGA with intact ventricular septum takes on the characteristics and wall thickness of a pulmonary ventricle and may not be adequate to support the systemic circulation.

The most common clinical finding in the infant with TGA is cyanosis (arterial PO_2 of 25 to 40 mm Hg), which will vary in degree depending on associated anomalies. Typically, the cyanosis is more pronounced when the ventricular septum is intact and is often present at birth. The development of cyanosis later in infancy is usually associated with the presence of a significant VSD. Congestive heart failure may be the predominant clinical finding in patients with a large VSD or PDA, and the combination of cyanosis and increased pulmonary blood flow is almost pathognomonic of TGA in the infant. Symptoms of cardiac failure rarely present in the first week of life but commonly appear by 1 month of age as pulmonary vascular resistance decreases and pulmonary blood flow becomes excessive, even in the patient with an intact ventricular septum.

DIAGNOSIS

Physical Examination

Cardiac examination typically reveals a mildly overactive precordium, and 75% of patients with TGA and an intact ventricular septum have a soft systolic murmur. The second heart sound is typically single and loud because of the proximity of the aorta to the anterior chest wall, which may make assessment of pulmonary vascular resistance difficult.²⁰ End-diastolic gallop rhythms are often noted in patients with associated VSD. In the presence of a large PDA, the femoral pulses are often bounding. The liver may be enlarged in patients with a large systemic-to-pulmonary shunt and may be associated with tachypnea, intercostal retractions, and inability to successfully nurse. Children with significant valvular or subvalvular pulmonary stenosis often have a crescendo-decrescendo cardiac murmur along the left sternal border transmitted to the right clavicular area.

Diagnostic Studies

The electrocardiogram may be normal at birth but over time shows signs of increasing right ventricular or biventricular hypertrophy. Chest x-ray findings in D-TGA include an egg-shaped cardiac configuration, narrow superior mediastinum, and increased pulmonary markings with cardiomegaly.

The widespread use of fetal ultrasound techniques has resulted in the common antenatal diagnosis of TGA. This fact and the fact that most children with TGA are cyanotic in the first week of life have led to the initiation of treatment at a very early age. Whereas in the past, cardiac catheterization was generally necessary to confirm the diagnosis of TGA and to demonstrate the position of the cardiac chambers and the associated lesions, echocardiography is now usually all that is necessary in most cases. Echocardiographic views confirming a posterior

great vessel that divides into right and left pulmonary arteries and arises from the left ventricle in association with an anterior aorta arising from a right ventricle confirms the diagnosis of TGA.

The intracavitary shunts can be determined by Doppler echocardiography techniques, and several echocardiographic views can determine the size and location of VSDs with reference to the infundibular septum, the nature and size of atrial communications, the anatomy of the atrioventricular valves, and the presence and location of significant degrees of subpulmonary stenosis. In addition, in most cases the origins and anatomic distributions of the coronary arteries can be adequately visualized by echocardiography. Because most coronary arterial variations can be successfully addressed at operation, identification of the origins of the coronary arteries is usually sufficient by echocardiography to preclude angiography. Cardiac catheterization is now indicated only in infants in whom inadequate shunting is noted or in infants with associated intracardiac or extracardiac abnormalities that require clarification. It is usually reserved for the purpose of enlarging the interatrial septal communication in those patients with significant clinical instability characterized by acidemia or severe hypoxemia (see following).

PREOPERATIVE MEDICAL MANAGEMENT

Patients who are good anatomic candidates for an arterial switch procedure and have acceptable arterial oxygen saturation are generally referred for early operation if the clinical condition permits. Prostaglandin E1 is usually administered to maintain ductal patency, increase pulmonary blood flow, and improve stabilization of patients before early operative repair. Because relative dehydration can decrease the degree of interatrial shunting, volume infusions may improve hemodynamics in infants presenting with TGA and intact septum early in life. A major development in the treatment of TGA occurred in 1966 when Rashkind and Miller reported the use of a balloon catheter technique to enlarge the ASD in patients with TGA, causing improved early physiologic stability.²² If there is significant instability, as evidenced by persistent acidemia or hypoxemia despite conservative measures, the mainstay of management has become a Rashkind balloon atrial septostomy.

In the neonate with TGA, left atrial pressure is usually greater than the right atrial pressure. The pressure in the pulmonary (left) ventricle is dependent on the presence or absence of a VSD, valvar or subvalvar stenosis, the age of the patient, and the pulmonary vascular resistance. If inadequate interatrial shunting is noted, a Rashkind atrial septostomy is performed.²² A balloon-tipped catheter is passed through the systemic veins, through the right atrium and foramen ovale, and into the left atrium; the balloon is inflated and pulled vigorously across the atrial septum to tear the foramen ovale, improving the admixture of pulmonary and systemic venous blood and tissue oxygen delivery. Although this procedure is usually performed at cardiac catheterization, it can be performed in the intensive care unit with echocardiographic guidance

in children who are very unstable. Performance of a Rashkind atrial septostomy results in decompression of the left ventricle and therefore may result in poor left ventricular performance if a subsequent arterial switch procedure is delayed.

SURGICAL MANAGEMENT

Surgical Correction

Satisfactory correction of TGA results in rerouting of systemic venous blood to the pulmonary circulation and the pulmonary venous blood into the systemic arterial circulation. This may be accomplished at the atrial, the ventricular, or the great arterial level. The earliest repairs of TGA involve rerouting of the systemic and pulmonary venous returns at the atrial level, resulting in a physiologic but nonanatomic repair, as the morphologic right ventricle continues to function as the systemic ventricle. Both ventricular (Rastelli) and great arterial (arterial switch, aortic translocation) repairs are anatomic corrections, resulting in a morphologic left ventricle as the systemic ventricle.

Palliative Operations

Reported by Blalock and Hanlon in 1950, initial surgical therapy for TGA involved creation of an ASD using a closed technique to increase the mixing between systemic venous and pulmonary venous circulations.⁶

Although the early mortality rate was high with this operative approach, successful creation of an ASD resulted in significant palliation in many of these children. The introduction of the balloon atrial septostomy has essentially eliminated the need for operative atrial septectomy. Infants with associated cardiac abnormalities and a thick atrial septum who are considered for later atrial baffle repair may benefit from the Blalock-Hanlon technique, although the safety of cardiopulmonary bypass (CPB) has resulted in the common use of open atrial septectomy in these patients.

Pulmonary arterial banding has been used for palliation in patients with TGA and VSD in young infants who have intractable congestive heart failure until operative repair at 3 to 6 months of age. Because the results from use of the arterial switch procedure and VSD closure in infancy have improved, banding in most cases is unnecessary because complete repair can be accomplished in the neonatal period. Therefore, banding of the pulmonary artery has now been limited to very small neonates who might benefit from delay in corrective operation, patients with complex TGA for whom delayed repair is planned (i.e., LVOT obstruction), patients presenting late with TGA and intact ventricular septum who require preparation of the left ventricle prior to receiving an arterial switch operation, and patients who develop right ventricular dysfunction and failure after atrial baffle operations as a component of staged conversion to an arterial switch repair (see below). Pulmonary arterial banding in TGA is a delicate procedure, because limitation of pulmonary blood flow results in significant hypoxia and

metabolic acidosis, and loose banding results in inadequate protection of the pulmonary vascular bed and poor development of the left (pulmonary) ventricle. Thus, in many situations in which the left ventricle is prepared for conversion to an arterial switch procedure, banding must be associated with creation of an aortopulmonary shunt to maintain adequate pulmonary blood flow and prevent hypoxemia and ventricular dysfunction.

Atrial Repairs

Initial attempts to reverse the transposed vessels in patients with TGA by both Mustard and Bailey and their colleagues were frustrated by their inability to maintain coronary perfusion and by poor function of the anatomic left ventricle.^{1,23} Thus, initial surgical therapy was directed toward atrial transposition of pulmonary and systemic venous returns. In 1952, Lillehei and Varco transferred the right-sided pulmonary veins to the right atrium and connected the inferior vena cava to the left atrium.²⁴ A successful modification of this technique using an allograft to connect the inferior vena cava to the left atrium was described by Baffes in 1956.²⁵ In 1955, Albert suggested the concept of switching the atrial septum so that caval return was directed to the left ventricle and pulmonary venous return to the right ventricle at the atrial level.²⁶ This atrial switch concept was first successfully accomplished by Senning in 1959, using an ingenious technique for relocating the walls of the right atrium and the atrial septum.²⁷ In this operation, pulmonary and systemic venous return was rerouted by incising and realigning the atrial septum over the pulmonary veins and using the free right atrial wall to create a pulmonary venous baffle (Fig. 125-3). The Senning operation was not associated with a

high survival rate at first because of its complexity and because of the fact that the operation was performed in children between 1 and 2 years of age or children with a VSD, and significant pulmonary vascular obstructive disease had already developed in many of these children.

In 1964, Mustard described an alternate procedure for intra-atrial repair excising the atrial septum and creating a large interatrial baffle of pericardium to redirect pulmonary and systemic venous blood (Fig. 125-4).²⁸ This repair resulted in a larger atrial size than the Senning operation. In the Mustard operation, creation of a virtual common atrium is necessary with resection of the atrial septum and the ridge of tissue between the superior vena caval entrance and the superior aspect of the atrial septum. Inadequate resection of the atrial septum has resulted in the occurrence of baffle obstruction of the systemic venous return to the heart. Early results with the Mustard operation were markedly improved over the previously reported Senning repairs and reflected the significant number of patients in Toronto who had had successful Blalock-Hanlon atrial septectomies early in life. Because of its technical simplicity, the Mustard operation became the most commonly performed procedure for transposition during the 1960s, and it became clear that repair in the first few months of life could be accomplished with a low operative mortality rate and improved results compared with repair at a later age. In 1970, the Senning procedure reemerged as the persistent problems of baffle obstruction and arrhythmias following the Mustard operation became well defined, and the ability to use autologous tissue for the atrial reconstruction became a preferred approach. Performing the Senning operation in infancy after successful balloon atrial septostomy became the preferred technique in many centers.

FIGURE 125-3 ■ The Senning operation. **A**, View from the right atrium showing incision lines (*dashed lines*) to create a flap of the posterior atrial septum and an incision into the base of the coronary sinus. **B**, The posterior flap of atrial septum is augmented with a piece of pericardium and sutured inferiorly over the origins of the pulmonary veins in the left atrium. The posterior wall of the right atrium is then sutured to the anterior portion of the atrial septum, baffling the vena caval return across the septum to the mitral valve. **C**, After completion of the venous baffle, the anterior wall of the right atrium is sutured to an opening made in the left atrium posterior to the interatrial septum at the entrance point of the right pulmonary veins, baffling the pulmonary venous blood over the systemic venous pathway into the right ventricle. **D**, Completed suture line showing repair with autologous tissue.

FIGURE 125-4 ■ The Mustard operation. **A**, Longitudinal incision is made in the right atrium away from the sinus node. **B**, The posterior aspect of the atrial septum is excised, creating a wide opening for baffling of the venous blood into the left atrium (*dotted lines*). **C**, The coronary sinus is cut back into the left atrium to avoid suturing near the atrioventricular node. Raw margins of atrial septum may be oversewn. The suture line for the placement of the baffle around the pulmonary veins is noted with the dotted line. **D**, Dacron or pericardium is used to baffle the vena caval blood flow to the left atrium across the mitral valve. Completion of this baffle allows venous blood to enter the right atrium and cross the tricuspid valve to the aorta.

Outcome after Senning and Mustard Operations

The Senning and Mustard operations share the feature of placing the right ventricle and the tricuspid valve in the systemic circulation. The children who undergo these operations are physiologically, but not anatomically, repaired. Both of these operations theoretically create the substrate for late complications. The first atrial switch type operation was described in the 1950s, and ample time has passed to observe and evaluate the results.

Overall outcomes of these two operations have been good. As techniques improved, the use of either Senning- or Mustard-type repairs in infancy was noted to be associated with a lower incidence of cerebral thrombosis and hypoxic injury as a result of cyanosis and peripheral emboli from right-to-left shunting. A standard approach developed using balloon atrial septostomy in infancy followed by the elective repair in infants between the ages of 3 and 8 months. Operative mortality rates in many larger series ranged between 2% and 10%, even for patients in early infancy.²⁹⁻³¹ Long-term actuarial survival rates for all patients with TGA undergoing atrial switch procedures is reported to be 88% at 10 years, 76% to 82% at 20 years, and 74% to 77% at 25 years.³² Results are slightly better in isolated TGA compared with TGA associated with VSD or other complicating conditions.

Late systemic (right) ventricular dysfunction occurs in 5% to 25% of patients. It is the most common cause of late mortality, being the cause of death in approximately

6% of patients in one large series.²⁹ Several challenges exist in following these patients. The reported incidence of late right ventricular dysfunction is variable. However, if right ventricular function is evaluated objectively, the systemic right ventricle virtually always functions abnormally compared with controls.

Echocardiographic analysis of right ventricular longitudinal shortening shows that right ventricular function could be judged abnormal in all 20 patients studied, depending on the parameter evaluated.³³ However, there has also been some difficulty in predicting which patients with measurable right ventricular dysfunction will progress and require further intervention. It has been suggested that late right ventricular dysfunction may be at least partially the result of perfusion defects, which are common in these patients, although the cause is unclear.³⁴ Another group suggests that marked increase of the right ventricular muscle mass (hypertrophy) in response to systemic afterload may be a contributor.³⁵

Late functional outcome has been reported to be good. One series with good long-term follow-up reported 66% of patients in New York Heart Association (NYHA) class I and 29% in class II.³² It should be noted that even in the asymptomatic patients, a significant percentage had suboptimal maximal oxygen uptake (MVO_2) when tested. A similar finding was noted by Ebenroth, who studied patients an average of 14 years after surgery and found that 75% had normal right ventricular ejection fractions and 84% perceived themselves to be in good health, but only 51% had normal exercise tolerance.⁴¹

Varied results from exercise testing in these patients have been reported. One study showed a decrease in the normal cardiovascular response to exercise over time.³⁶ Another showed no decrease in MVO_2 with aging, but maximal oxygen consumption in these patients was significantly less than that of individuals without congenital heart disease.³⁷ This finding was corroborated by a study using magnetic resonance imaging in a group of adult patients after atrial level repair.³⁸ Abnormal cardiac recovery after exercise was found despite the patients being in NYHA class I and on no medications. An echocardiographic study suggested that abnormalities in function during exercise might be caused by impaired atrioventricular transport leading to reduced stroke volumes with stress.³⁹

Late arrhythmias are common after atrial switch procedures. At a median follow-up of 23 years, only two thirds of patients are in sinus rhythm, and two thirds have experienced supraventricular tachycardia.³² Risk factors for supraventricular tachycardia include pulmonary hypertension and a history of junctional rhythm. A separate study found arrhythmias in 22% of patients an average of 23 years after the Mustard procedure and found that ventricular function was compromised in these patients compared to Mustard patients without arrhythmias, suggesting that late arrhythmias are a marker for systemic ventricular dysfunction.⁴⁰ By 14 years after surgery, pacemakers were required in 22% of patients for either sick sinus syndrome or bradycardia because of heart block.⁴¹

Treatment for right ventricular dysfunction in these patients is evolving. Because of the hypertrophy of the right ventricle, some have suggested angiotensin-converting enzyme (ACE) inhibition, which has been shown to be beneficial in left ventricular remodeling. Although there are some encouraging data for this patient population, results have not been consistent.⁴² There are several surgical options to deal with late right ventricular failure after atrial switch: tricuspid valve repair or replacement if the ventricular dysfunction is associated with severe tricuspid regurgitation, conversion to an arterial switch, or heart transplantation. Because severe right ventricular dysfunction is frequently, if not always, associated with severe tricuspid regurgitation in these patients, the first option seems an attractive one. The results have been disappointing, however, with no significant improvement in function after surgery.²⁹

In summary, overall functional results after atrial switch procedures have been good after mid- and long-term follow-up. However, assessment of the systemic right ventricle reveals that its function is not normal in the systemic circulation. There are significant risks for progressive late right ventricular dysfunction and late arrhythmias, and for heart failure. As patients age, they must be followed closely for these complications, and means of treatment must be refined.

Arterial Repairs

In spite of the excellent results with the Mustard and Senning procedures, both operations are associated with physiologic, and not anatomic, correction. The

morphologic right ventricle remains the systemic ventricle in these patients, and although most patients have had many years of successful function of the right ventricle as the systemic ventricle, concerns about its long-term function remain. Although it may not be inevitable that systemic morphologic right ventricles will fail with time, a considerable number of patients have now returned after an atrial baffle operation with complications of intractable atrial arrhythmias and right ventricular failure. Thus, there has been increasing interest in the more anatomic correction by the arterial switch operation in hopes of preventing late ventricular dysfunction and arrhythmias.

The success with the atrial switch operations for TGA with intact septum did not translate to repair of transposition with large VSD. Disappointing results with VSD closure and atrial repair in this group of patients continued to be a stimulus for development of an arterial switch procedure that was first successfully performed by Jatene and colleagues in 1975 and subsequently reported by Yacoub and coworkers.^{43,44} The success of the arterial switch procedure with reimplantation of the coronary arteries in some patients with TGA and VSD led to reintroduction of this technique for patients with intact ventricular septum. Yacoub's initial attempts in patients with TGA and an intact ventricular septum were unsuccessful in 1972; however, additional reports by 1976 suggested that such repair was possible in infancy.⁴⁵ Early mortality with the arterial switch in infancy was related to the development of pulmonary vascular obstructive disease and the complexity of the operation and to the fact that the left (pulmonary) ventricle was not prepared to sustain systemic pressure. Therefore, initial approaches included pulmonary arterial banding as a first stage, followed by arterial switch at a later time.⁴⁵ However, improvements in the techniques of coronary transfer, myocardial protection, and neonatal vessel reconstruction have resulted in improved survival statistics in the arterial switch. Brawn, Castañeda, Quaegebeur, and their associates subsequently demonstrated the feasibility of repair of simple transposition in the first few days of life by arterial switch operation while the pulmonary ventricle has a relatively high pressure producing results that rival or exceed those of atrial baffle operations.⁴⁶⁻⁴⁸

Technique

The principles of successful anatomic correction include dividing the aorta and pulmonary artery, excising the origins of the coronary arteries with a button of aortic wall, repositioning the coronary arteries to the posterior great vessel (pulmonary artery), and reconstructing each ventricular outflow to the appropriate distal vessel (Fig. 125-5). The details of the operative techniques, however, vary from one institution to another. The procedures are performed with a median sternotomy incision and the use of CPB and hypothermia, although hypothermic circulatory arrest is used for the procedure in varying degrees in many institutions. After the median sternotomy is performed, a portion of the anterior pericardium is excised for autologous patch reconstruction of the defects in the anterior great vessel. The pericardium may be used fresh

or fixed in glutaraldehyde to make it easier to manipulate during the operation. The ligamentum arteriosum or ductus arteriosus is dissected, and the pulmonary arteries are mobilized to the bifurcation of the vessels in the hilum of the lung bilaterally. It is important to mobilize the pulmonary arteries freely to permit anterior relocation of the pulmonary bifurcation without distortion of the pulmonary artery or aorta. The aorta is typically cannulated for bypass distally to allow room for manipulation of the proximal aorta during the reconstruction. After bypass is established, the ductus arteriosus is ligated and divided and the aortic end and pulmonary arterial end oversewn as necessary. The aorta is then clamped close to the aortic cannula and cardioplegia administered into the aortic root.

If a VSD is present, it is approached either through the right atrium across the tricuspid valve or, occasionally, through the anterior great vessel. The aorta is then transected above the level of the coronary ostia and the pulmonary artery is transected just below the bifurcation, with care not to carry the incision into the left pulmonary artery. The pulmonary artery bifurcation is brought anterior to the aorta (the Lecompte maneuver). The coronary ostia are examined and excised from the anterior great vessel with a button of aortic wall extending down into the base of the sinuses of Valsalva. The epicardial course of the coronaries is then mobilized adequately to allow turning the coronary ostia to the posterior great vessel without kinking of the epicardial course. In rare cases, the small conal branches of the coronaries may need to be sacrificed to permit adequate mobilization. An incision is then made in the posterior great vessel at the site for reattachment of the coronary ostia, and a medially based flap incision is created to allow takeoff of the coronary ostia without tension or kinking, and the coronary ostia are sewn to the incisions in the posterior great vessel.

Although transfer of the coronary arteries is one of the most technically challenging and important parts of the arterial switch procedure, experience and refinements in technique have made it possible to deal with most variations in coronary anatomy. When both coronaries come off a single sinus with the left coronary orifice near the commissural attachment of the aortic valve, it is possible to mobilize the commissure and excise the coronary arteries in the usual fashion. Alternatively, if the coronary ostia are close together or if there is a single coronary artery, a single button containing the adjacent ostia or common orifice can be excised and transferred to the posterior great vessel. This is done in a side-to-side fashion, and the distal aorta is fashioned to create an anterior flap that is sewn over the button to complete the anastomosis (see Fig. 125-5K-M). Another concept that is helpful in dealing with single coronary arteries is to translocate the button higher onto the posterior great vessel to alleviate any kinking that may occur with rotation of the flap.

After completion of the coronary anastomoses, the distal aorta is anastomosed to the posterior great vessel to which the coronary arteries have been transferred. Additional cardioplegia may be administered at this time to check for hemostasis of the suture lines and to confirm

good myocardial perfusion without kinking of the coronary anastomoses. The defects in the anterior great vessels from which the coronary arteries have been excised are then repaired with a generous portion of pericardium. The anterior great vessel is sutured to the pulmonary artery bifurcation, with care being taken to avoid tension on the pulmonary arteries that may interfere with symmetrical pulmonary blood flow. Finally, the ASD is closed either primarily or with a small patch of pericardium, and the atrium is closed. In the situation in which the great vessels are side to side rather than antero-posterior, it may be advisable to leave the pulmonary confluence posterior to the aorta and open the right pulmonary artery, closing the pulmonary bifurcation to transpose the opening in the pulmonary artery more to the right than usual. This may facilitate reconstruction to the right ventricle.

After completion of the repair, left atrial and right atrial lines are placed for postoperative monitoring and temporary pacemaker wires applied. The infant is weaned from bypass, maintaining a systemic pressure of approximately 60 mm Hg to prevent distention of the newly systemic left ventricle.

Postoperative Management

Continuous sedation with mechanical ventilation and moderate inotropic support are usually used in the first 12 to 18 hours after repair, as in other infants undergoing complex congenital heart repair. Neuromuscular blockade may be administered continuously during this period, or, in patients who are anticipated to have a more stable course and may be candidates for earlier extubation, it may be used intermittently on an as-needed basis. If the patient is stable after the initial postoperative period, sedation is reduced and the patient is weaned from the ventilator over the next 24 to 48 hours. After extubation, inotropic support is discontinued, umbilical lines are removed if they are present, and enteral feeding is commenced. Once enteral intake is satisfactory, the rest of the support equipment can be removed in preparation for discharge. The current usual hospital stay for correction of TGA is 10 to 12 days.⁴⁹⁻⁵¹

Outcome after Arterial Switch Operation

Early and Mid-term Follow-up. Initial results of the arterial switch operation would be considered poor by today's standards. Jatene's original series included a mortality of approximately 60%. This high early mortality rate was duplicated in other series, yet surgeons pressed on with this operation with the belief that it was physiologically superior to atrial level switch procedures.

Despite the early outcomes, results in the current era are excellent. The early mortality rate is less than 4%, even when complex forms of transposition are included in the analysis. Despite the excellent survival data, however, reoperations are required in 5% to 10% of patients. Reoperation for coronary lesion has been reported in approximately 2% of survivors, but frequency depends on screening protocols.⁵²

FIGURE 125-5 ■ The arterial switch operation. **A**, Cannulation site for cardiopulmonary bypass in the arterial switch operation. Single atrial or bicaval venous cannulation can be used. The ductus arteriosus is suture ligated and divided between sutures. **B**, Division of the ductus arteriosus and ascending aorta after initiation of cardioplegic arrest. **C**, Excision of the left and right coronary ostia with a button of aortic wall. **D**, Excision of corresponding segments of the posterior great vessel wall to which the coronary arteries will be reimplanted. Alternatively, medially based flap incisions can be used. **E**, Suturing of the coronary ostial buttons to the posterior great vessel. **F**, Completed anastomosis of the reimplanted coronary arteries. In some cases, the coronary buttons can be approximated together in the midline. **G**, Augmentation of the medial aspect of the anastomosis to prevent kinking is occasionally necessary although less common if medially based flap incisions are used for coronary reimplantation. **H**, If juxtacommissural origins of either coronary artery or both coronary arteries from the facing sinuses are present, excision of a portion of the native aortic valve may be necessary to allow mobilization. **I** and **J**, Separation of the coronary arteries is done, if possible, to prevent distortion and to provide easier implantation.

FIGURE 125-5, cont'd ■ **K**, If right and left intramural coronary arteries are present, the aortic coronary flap is left in place and sutured along the cephalic border to an incision in the anterior neo-aorta. **L** and **M**, A pericardial patch is then used to provide unrestricted entrance of blood into the coronary ostia. **N**, After completion of the coronary transfer, the distal aorta is anastomosed to the neo-aorta. **O**, The pulmonary bifurcation is brought anterior to the aorta in the Leconte maneuver. **P**, The defect in the aorta from which the coronary arteries have been excised is augmented with a pantaloon-shaped patch of pericardium. **Q**, The pulmonary bifurcation is then anastomosed to the augmented aorta. In most cases, pericardium is not sutured completely around the aorta to create a complete pericardial tube. **R**, Completed anastomosis of the pulmonary artery anterior to the new aorta.

In most series, reoperation is most commonly indicated for right ventricular outflow tract (RVOT) lesions, which may occur in up to approximately 10% of patients.^{53,54} However, technical modifications to the procedure are thought to be responsible for a reduction in reoperation for RVOT obstruction to less than 2% to 3%. More long-term follow-up data are now available on children undergoing neonatal arterial switch. Prifti and colleagues reported the results of a large series of patients with a mean follow-up of 3.5 years. The early mortality rate was 12.7% but significantly lower (5.7%) for those children with isolated TGA. Actuarial survival rates were 98%, 93%, and 91.5% at 1, 3, and 5 years, respectively, after surgery. Freedom from reoperation was 95%, 90.5%, and 83% at the same time points. The presence of a VSD adversely affected survival. Predictors of reintervention included VSD, coronary anomalies, aortic coarctation, and LVOT obstruction or moderate pulmonary stenosis.⁵⁵ Another series of 181 patients with a mean follow-up of 5.8 years revealed a 5.5% early mortality rate and 92% survival rate at 5 and 10 years. VSD was a risk factor for early and late death.⁵⁶ The largest series in the literature with long-term follow-up was reported in 2001 and included data on 1095 patients from a single institution. Mean follow-up was approximately 5 years. Early mortality was 8.6%. Survival was 89% at 1 year and 88% at 10 and 15 years (including those patients who died early). Simple TGA was found to be associated with improved survival (92% vs. 80% for complex TGA). Freedom from reintervention was 90%, 83%, and 82% at 5, 10, and 15 years, respectively, of follow-up.⁵⁷

Although the early mortality rate seems high in some of the larger series that include earlier results, the current operative mortality rate is approximately 2% to 3%.⁵⁸⁻⁶⁰ Analysis of large series found complex anatomy (large VSD, multiple VSDs, Taussig-Bing anomaly but not aortic coarctation), coronary anomalies, previous operation, and prolonged bypass time to be risk factors for early death.⁵⁸ Another study identified female gender and preoperative instability as risk factors for operative mortality and suggested that in the current era, abnormal coronary patterns were less of a factor. A recent review of contemporary data (1999-2005) reported that coronary anatomy was not a factor affecting survival and that factors affecting mortality included gestational age less than 36 weeks and bypass time less than 150 minutes.⁶¹

Although this seems to be true, a single coronary ostium and intramural coronary course are still risk factors for mortality in some studies.⁶² Coronary artery-related problems are the most common cause of early death, followed by right ventricular failure and pulmonary hypertension.⁶⁰ It has been suggested that risk factors for late death include an unusual relationship of the great vessels, single coronary ostium, prolonged bypass time, and coarctation of the aorta, although none of these proved to be significant in a multivariate analysis.⁵⁸

Cardiac rhythm abnormalities are unusual after arterial switch operation with over 90% of patients in normal sinus rhythm. Left ventricular function is generally normal. Most patients (>95%) are in NYHA functional class I at long-term follow-up.⁵⁹ Aortic stenosis is very

rare, and mild aortic insufficiency is seen in approximately 10% of patients. Although there was initial concern that the neo-aortic root dilated disproportionately, raising the concern of progressive aortic insufficiency, longitudinal analysis has shown that the neo-aorta undergoes dilation during the first year of life but then tends toward the normal size as further growth occurs.⁶³ Pulmonary stenosis is seen slightly more frequently.⁵⁶ Very few patients are taking cardiac medications at mid-term follow-up.^{60,64} Late coronary artery problems are rare.

Late Follow-up. A recent review of long-term outcomes compared those of the arterial switch operation to those of the Mustard and Senning atrial switch operations.⁶⁵ It was reported that the change from the atrial to the arterial switch in 1983 has led to improved long-term survival (Fig. 125-6) but that reoperation rates are similar. Interestingly, the reoperations performed following the arterial switch operation were predominately targeting RVOT lesions, but approximately 2% of patients required aortic valve replacement. Importantly, systemic ventricular dysfunction occurred in 9.1% of patients after atrial switch but only 0.4% of patients after the arterial switch.

Whereas early and long-term survival favors the arterial switch operation, the late neurologic outcome has been investigated. Despite evidence of neurologic impairment 3 to 4 years after arterial switch operation, these effects showed moderation at later follow-up.⁶⁶ More long-term longitudinal follow-up of patients entered into the Boston circulatory arrest study has shown a gradual moderation in developmental disabilities manifest in early childhood.^{67,68} Although this group shows that behavioral dysfunction (attention and executive functions) persists among these patients, few differences were found to be attributable to the method of operative treatment. This underscores the increasing awareness that children treated for congenital heart disease are at increased risk for behavioral and neuropsychiatric disabilities well into their childhood.⁶⁹

In summary, outcomes after arterial switch are generally very good. Follow-ups to date suggest that, as expected, the results are superior to atrial switch operations in terms of late ventricular function, freedom from arrhythmias, and functional status. The rapidly decreasing mortality for arterial switch operations has resulted in this surgical approach becoming the standard corrective surgical procedure at the present time and results in both an anatomic and a physiologic reconstruction of this cardiac defect.

Fate of the Neo-aortic Valve and Late Coronary Lesions. The arterial switch operation is generally considered a corrective operation because no future operations are planned. However, several longitudinal studies are reporting a significant rate of reoperation. Reoperation on the RVOT is generally the most common indication and is related to inadequate growth at the neopulmonary anastomotic site. However, progressive neo-aortic dilation and late coronary artery lesions are also being recognized as potential surgical problems.

FIGURE 125-6 ■ **A**, Estimated survival among 929 hospital survivors after correction, stratified by type of operation: Senning versus Mustard versus arterial switch. **B**, Estimated freedom from reoperation among survivors, stratified by type of operation: Senning versus Mustard versus arterial switch. (From Horer, J, Schreiber C, Cleuziou J, et al: Improvement in long-term survival after hospital discharge but not in freedom from reoperation after the change from atrial to arterial switch for transposition of the great arteries. *Thorac Cardiovasc Surg* 137:347–354, 2009.)

In a recent review, Schwartz and coworkers reported that aortic root dilation (z-score > 3) is common after arterial switch operation, affecting approximately 50% of survivors at 10 years. Root dilation did not necessarily translate into aortic insufficiency—only approximately 7% of patients demonstrated significant aortic insufficiency (moderate or greater). However, approximately 5% of patients required neo-aortic valve or root surgery at 10 years. The authors reported that older age at the time of repair, VSD, and a previous pulmonary artery band were independent risk factors for aortic insufficiency in these patients.⁷⁰ Longer-term follow-up has

similarly shown that aortic root dilation is present in 66% of patients 20 years after arterial switch operation but that surgery on the neo-aortic root or valve remains uncommon. It is important to note that left ventricular function is preserved in these patients.⁷¹

A recent review of a European center's experience reported an incidence of aortic insufficiency that increased with time, with 2% of patients requiring aortic valve replacement an average of 11 years after the arterial switch operation. Independent risk factors identified for late aortic valve replacement were the presence of LVOT obstruction and aortic insufficiency at 1 year.⁷²

Although coronary issues are thought to be rare among hospital survivors after the arterial switch operation, Raisky and colleagues found that coronary lesions were detectable in 12% of survivors undergoing coronary angiography an average of 33 months after arterial switch. Forty-five percent of angiographically documented coronary lesions were observed in the absence of ischemia as assessed clinically and by myocardial perfusion imaging. Of the 55% of patients undergoing revascularization, 17 of 19 revascularized lesions resided within the left coronary system. Whereas 16 of 19 patients were treatable with angioplasty, 3 underwent surgical revascularization without any mortality.⁷³

Because of the excellent results obtained with the neonatal arterial switch operation, this has become the standard of care. However, there are occasions when the diagnosis of TGA with intact ventricular septum might be delayed, or when no surgery is immediately available, and late arterial switch operation is considered. In general, primary arterial switch operation within 3 weeks of life is noncontroversial. However, because of progressive deconditioning of the postnatal pulmonary left ventricle, primary arterial switch operation has been considered high risk, and rapid two-stage arterial switch operation has been advocated by some. However, several groups have reported that the rapid two-stage arterial switch operation results in impaired left ventricular contractility in up to 25% of patients, an increased incidence of neo-aortic insufficiency, and RVOT obstruction. Bisoi and associates reported the combined early mortality rate of the rapid two-stage arterial switch operation is higher than that for the late primary arterial switch operation (55% vs. 14%).^{74–77}

These results have prompted groups to perform primary arterial switch operation on children presenting later in infancy. When Kang and colleagues reported their outcomes for 105 patients undergoing late primary arterial switch operation (older than 3 weeks), they found no difference in hospital mortality (3.8% vs. 5.5%) or ECMO (5.7% vs. 3.6%) when compared to early primary arterial switch operation.⁷⁸

Similar results have been published by Edwin and coworkers, who reported no mortality (two ECMO) in six patients undergoing primary arterial switch operation between the ages of 31 and 66 days.⁷⁹

These experiences suggest that the rapid two-stage arterial switch operation may be unnecessary for most patients presenting well into infancy and that primary arterial switch operation, with ECMO backup, is justifiable.

COMPLEX TRANSPOSITION

Anatomic Variants of Transposition of the Great Arteries

Although discordant relationship between the ventricles and great vessels is an integral component of transposition, associated defects often dominate the clinical presentation and management of these infants. The term *complex transposition* refers to those defects in which there are conotruncal anomalies in addition to TGA. The associated conotruncal defects include malalignment or deviation of the conal septum into either the LVOT or RVOT or persistence of a conus over the left ventricle separating the mitral valve from the semilunar valve, also called the Taussig-Bing anomaly. Together these complex forms account for 10% to 15% of all transposition cases.⁸⁰

Conal Septum

The conal septum separates the two semilunar valves and forms part of the septation of the common arterial trunk, present early in fetal cardiac development, into the aorta and the pulmonary trunk. Although abnormal development of the conus with regression of the subpulmonary component rather than the subaortic component has been proposed as the cause of transposition, the position, orientation, and size of the conal septum may vary independent of ventriculoarterial connection.⁸¹ Thus, a prominent conal septum that deviates posteriorly can cause left ventricular outflow obstruction; similarly, anterior deviation of the conal septum can result in right ventricular outflow obstruction. In hearts with normally related great arteries, when the conal deviation is associated with a conoventricular septal defect, the downstream consequences of the ventricular outflow obstruction are hypoplasia or atresia of the affected great artery as seen in interrupted aortic arch (left ventricular outflow obstruction) and tetralogy of Fallot (right ventricular outflow obstruction). In transposition, however, the affected downstream circulation is the inverse with left ventricular outflow obstruction resulting in decreased pulmonary trunk blood flow and right ventricular outflow obstruction resulting in aortic arch hypoplasia, interruption, or both.^{82,83}

Transposition and Left Ventricular Outflow Tract Obstruction

LVOT obstruction in an infant with TGA can occur in the presence or absence of a VSD. In patients with an intact ventricular septum, most often the pressure gradient measured across the outflow tract is a result of dynamic displacement of the interventricular septum posteriorly as a result of the pressure difference between the right (systemic) and left (pulmonary) ventricles, with the latter functioning at lower pressures.

Once the left ventricle assumes the systemic circulation following an arterial switch, the septum usually bows toward the right ventricle and the pressure gradient disappears. A fixed obstruction from a prominent conal

septum deviated posteriorly or a fibrous ridge or muscle bundle is uncommon in the absence of a conoventricular septal defect and, in most cases, can be resected and does not preclude an arterial switch operation.

LVOT obstruction in the presence of a conoventricular septal defect most often results from posterior deviation of the conal septum. In long-standing obstruction, a fibrous ridge or even fibromuscular tunnel can develop, further increasing the degree of obstruction. The obstruction is usually subvalvar but can be associated with pulmonary valve hypoplasia or dysplasia (bicuspid valve and/or thickened leaflets) precluding the use of this valve for an arterial switch procedure. The degree of obstruction in LVOT obstruction with a VSD is often more severe than in TGA with intact septum, and the obstruction often progresses early in infancy during the first few months of life requiring surgical intervention because of progressive cyanosis.

Transposition and Right Ventricular Outflow Tract Obstruction

Similar to LVOT obstruction, deviation of the conal septum, in this case anteriorly into the RVOT, is the most common cause of obstruction to flow into the systemic circulation. In transposition, RVOT obstruction is almost always associated with a malalignment-type conoventricular septal defect and is also frequently associated with double-outlet right ventricle, also called Taussig-Bing anomaly. In this latter defect, there is persistence of a conus or infundibulum under the pulmonary trunk, resulting in muscular separation between the mitral and pulmonary valve annulus. This complex lesion accounts for 5% to 7% of transposition cases based on autopsy series.⁸⁴ Associated defects include downstream hypoplasia of the aortic valve and aortic arch with coarctation. In some infants, the degree of aortic valve and arch hypoplasia is severe, requiring maintenance of a patent arterial duct to achieve adequate systemic perfusion. Hypoplasia of the right ventricle and tricuspid valve has also been described in this complex to a degree that a two-ventricle repair was not possible.⁸⁵ Often enlargement of the RVOT is necessary in conjunction with an arterial switch operation to prevent the development of subpulmonary obstruction. Hypoplasia of the aortic valve annulus in transposition can vary in degree and in severe forms requires a transannular patch along with an arterial switch to relieve right ventricular outflow obstruction.

In most cases of RVOT obstruction and transposition, there is a significant mismatch in diameter between the pulmonary trunk and the ascending aorta. This fact complicates the arterial switch procedure because enlargement of the ascending aorta and, if aortic arch hypoplasia is present, enlargement of the entire transverse arch and isthmus are required to achieve a hemodynamically satisfactory result.

Double-Outlet Right Ventricle with Transposition

Double-outlet right ventricle with TGA is often termed *double-outlet right ventricle with subpulmonary VSD* to

FIGURE 125-7 ■ Transposition with double-outlet right ventricle. The conal septum is positioned over the right ventricle. In cases in which there is deviation of the conal septum from this neutral position, the outflow semilunar valve and great artery often are hypoplastic.

describe the great vessel relationship to the right ventricle and to the VSD. Unlike double-outlet right ventricle with normally related great arteries, the vessel closest to the VSD in this case is the pulmonary trunk and determines the method of anatomic repair required for correction. Subpulmonary or subaortic obstruction can be associated with transposition and double-outlet right ventricle, usually resulting in hypoplasia of the downstream semilunar valve and great vessel. The relationship of the great vessels to each other often is that of a side-by-side arrangement with the aorta most commonly to the right of the pulmonary valve.

The VSD is described as a malalignment type because the conal septum does not meet the septomarginal trabecula, similar to double-outlet right ventricle with normally related great vessels (Fig. 125-7). The VSD can extend to the annulus of the tricuspid valve, and in these cases, the conduction tissue runs on the edge of the VSD in the posterocaudal margin of the defect starting at the junction with the tricuspid valve annulus.⁸⁶ In some cases, the VSD can extend to the inlet septum; this complicates the repair because the defect is partially covered by the septal leaflet of the tricuspid valve. In such cases, chordae from the tricuspid valve can attach to the crest of the septum and even straddle into the left ventricle. In most cases, however, the degree of straddling is limited and does not preclude a two-ventricle repair. Rarely, additional septal defects are present in the muscular septum or apical trabecular area, and these can be difficult to identify and close, particularly in the apical posterior septum.

Coronary Artery Anatomy

Coronary artery anatomy can also be variable with complex forms of transposition. Transposition and double-outlet right ventricle in particular is associated with unusual patterns of coronary artery anatomy, including a relatively high incidence of a single coronary artery giving rise to branches to both ventricles. The high association between side-by-side great vessels and unusual coronary artery pattern has been emphasized previously. In a detailed pathologic study, Uemura and associates found that a single coronary artery was present in 27% of hearts with a side-by-side great artery relationship.⁸⁷

Gordillo and colleagues have also described a higher incidence of unusual coronary artery pattern in double-outlet right ventricle with a subpulmonary VSD.⁸⁸ Coronary anatomy continues to be an important factor in anatomic repair of transposition, however, only when an arterial switch is contemplated as part of the repair. Although in most larger centers coronary artery pattern is no longer a significant risk factor for death, it can complicate the surgical procedure and may result in a higher rate of complications.

Aortic Arch Anatomy

Aortic arch anomalies occur in 7% to 10% of infants with transposition and VSD. This association is more common when the pulmonary valve overrides the ventricular septum, particularly in double-outlet right ventricle and transposition. A wide spectrum of arch obstruction exists from discrete coarctation at the level of the ductus to hypoplasia of the distal arch and even aortic arch interruption. The degree of severity of arch hypoplasia is thought to be associated with the degree of subaortic obstruction, usually from anterior deviation of the outlet or conal septum into the right ventricular outflow. Additionally, there can be relative hypoplasia of the tricuspid valve in comparison with the mitral valve, and in extreme cases, the degree of hypoplasia of the tricuspid valve can preclude a two-ventricle repair. It is important to recognize this association. Preoperative measurements of the atrioventricular valves normalized to body surface area can be most helpful in deciding surgical management.

Diagnosis and Preoperative Management

Echocardiography is usually the initial diagnostic study performed when complex congenital heart defects are detected because it provides not only the anatomic detail required to plan surgical repair but also physiologic information on valve function, presence, location, and severity of obstructions to flow, particularly in the outflow tracts of the ventricles as well as the pulmonary arteries and arch vessels. As with all echocardiographic studies, a systematic evaluation of chambers, connections, inflow and outflow valves, and ventricular size and function is imperative, particularly with difficult defects such as complex transposition. In addition, specific anatomic details—such as the relationship of the pulmonary root to the VSD, conal septal position, coronary artery pattern,

and chordal attachments of the atrioventricular valves with respect to the septum—are important for the development of a plan for surgical correction.

Cardiac catheterization is not required in most cases of complex transposition because echocardiography is usually sufficient to detail the anatomy and important physiologic features. Cardiac catheterization and angiography are therefore used to resolve specific questions where accurate pressure measurements are required, such as pulmonary artery pressures for calculation of pulmonary vascular resistance, or to measure the pressure gradient across a potentially restrictive VSD. Also, in cases in which a palliative procedure has been performed, catheterization and angiography are needed to identify potential anatomic distortion from the previous surgical interventions such as systemic-to-pulmonary shunts. Rarely is interventional catheterization required in infants unless there is a restrictive interatrial communication and inadequate mixing of blood from the pulmonary and systemic circuits, a situation more common in transposition with intact septum.

Transposition of the Great Arteries with Left Ventricular Outflow Tract Obstruction

Palliative Procedures. The pathophysiology of transposition results in cyanosis that often is unresponsive to oxygen therapy. When transposition is complicated by obstruction to the LVOT, cyanosis can be more severe, frequently worsening in the first few months of life. In the extreme, when there is atresia of the LVOT, pulmonary blood flow is entirely dependent on a patent arterial duct and/or systemic-to-pulmonary collaterals. In these cases, repair of this defect can be delayed by placing a systemic-to-pulmonary shunt and ligating collaterals or the arterial duct. The corrective procedure can then be deferred several months. In cases in which cyanosis is not severe, a systemic-to-pulmonary shunt is not indicated, and if delayed repair is contemplated, this can usually be deferred several weeks or months. The most common reason for delaying the corrective procedure is when resection of the left ventricular outflow is not feasible and a conduit will be required to establish right ventricle to pulmonary artery continuity (see [Rastelli Operation](#) section). The institutional philosophy at Children's Hospital Boston, however, is to achieve anatomic and physiologic correction of the cardiac defect as early in life as possible.

Surgical Technique. The preferred shunt procedure for TGA with LVOT obstruction is a modified Blalock shunt with an expanded polytetrafluoroethylene (PTFE) tube graft. In infants with a left aortic arch, the origin of the shunt is the base of the right subclavian artery, and the distal end connects to the right pulmonary artery. The surgical approach for a shunt is usually through a median sternotomy that provides access to the arch vessels and branch pulmonary arteries. The thymus gland is mobilized, and the innominate vein is freed from attachments to the pericardium and aorta. Because the course of the shunt will be parallel to the superior vena cava, tissue between the ascending aorta and superior

cava must be cleared. Once the innominate artery and right subclavian origin are dissected, the right pulmonary artery is mobilized from its origin to the bifurcation of the upper lobe. Heparin (50 U/kg) is administered to prevent thrombus formation in the vessels or the graft during insertion. The caudal side of the innominate-subclavian artery junction is identified for the anastomosis, and a curved vascular clamp is used for occlusion. The anastomosis is done with fine monofilament sutures (7-0 polypropylene), and care is taken not to damage the fragile intima of the innominate artery. The distal end is sewn to the cephalad side of the pulmonary artery, also with fine monofilament sutures. De-airing of the graft is performed, and brisk flow through the graft should be confirmed prior to completing the distal anastomosis. The graft is usually 3.5 mm in diameter for neonates and young infants and provides adequate pulmonary blood flow for several months until corrective surgery is performed. In some centers, a larger shunt (4.0 mm) is chosen in an effort to gain more time with palliation. This approach, although effective, runs the risk of producing pulmonary overcirculation in the early period after shunt insertion with complications such as inadequate renal perfusion and renal insufficiency or necrotizing enterocolitis. If a larger shunt is used, great care must be taken in the early postoperative period to maintain adequate systemic perfusion to avoid these complications.

Once the shunt is unclamped, the oxygen saturations should rise within seconds confirming adequate shunt flow. An additional indicator is a modest fall in diastolic pressure. The ductus arteriosus is typically ligated. Once stable, a single chest drain is left in the pericardial space and the sternum is closed. Low-dose heparin (10 to 20 U/kg/hr) can be continued in the postoperative period once mediastinal bleeding has subsided.

Corrective Procedures. Management of the LVOT obstruction in transposition depends on the severity and location of the obstruction. In cases in which the obstruction appears dynamic from leftward deviation of the interventricular septum because of systemic pressure in the right ventricle, an arterial switch procedure with closure of a VSD, when present, is the preferred method of correction. In these cases, the pulmonary valve annulus is within the normal range for the child's size, and instantaneous gradient across the left ventricular outflow, as estimated by echo Doppler, is less than 35 to 40 mm Hg in the presence of a small or closed arterial duct.

Transposition of the Great Arteries with Posterior Deviation of Conal Septum

In most cases in which the conal septum is the major source of left ventricular outflow obstruction and the pulmonary valve is adequate (z-score of -2.5 or better), the resection of the conal septum with closure of the VSD (when present) and an arterial switch procedure is the best option. This approach establishes anatomic repair and avoids the use of conduits, although there is a small but present risk of developing more severe LVOT obstruction later. Resection of the subpulmonary

obstruction is most often possible through the pulmonary trunk, by retracting the pulmonary valve leaflets. This approach also ensures adequate visualization of the hinge points of the leaflets because these can attach to the conal septum directly. The left ventricular outflow can also be seen through the mitral valve, although this approach is rarely better than through the pulmonary artery.

When the obstruction to the left ventricular outflow cannot be resected or is associated with pulmonary valve hypoplasia or severe dysplasia, the pulmonary root cannot be used to achieve a two-ventricle repair. In these cases, the aortic root arising from the right ventricular conus must be used for systemic flow and a conduit used to establish right ventricle to pulmonary artery continuity. There are two options to achieve this result: (1) the Rastelli operation, in which the aortic root is left attached to the right ventricle and left ventricular blood flow is diverted through the VSD to the aorta by means of a baffle, and (2) mobilization of the aortic root off the right ventricle, similar to a pulmonary autograft in normally related great vessels, and reimplantation of it into the opened left ventricular outflow, patch enlarging the left ventricular outflow and reimplanting the coronary arteries (autograft translocation and arterial switch operation). In both cases, a conduit is used to connect the right ventricle to the pulmonary artery bifurcation.

Rastelli Operation. For cases in which a large conoventricular VSD is present, Rastelli and colleagues described a procedure in which a synthetic semicircular patch is sewn to the edge of the VSD inferiorly and around the aortic annulus, diverting left ventricular flow through the VSD to the aorta.⁸⁹ The pulmonary root is closed, and a conduit is inserted between the right ventricle and the pulmonary artery. Frequently the VSD must be enlarged to prevent subaortic obstruction, and as described by Rastelli, the conal septum should be resected. The approach is via a sternotomy harvesting a patch of pericardium to be treated with glutaraldehyde (0.6% for 10 to 15 minutes), which may be required for pulmonary artery augmentation or for the gusset connecting the right ventricle to the conduit anteriorly. The main pulmonary artery and branches are dissected and mobilized to the level of the upper lobe bifurcation, similar to an arterial switch. Arterial cannulation at or near the level of innominate artery facilitates retraction of the ascending aorta, and bicaval cannulation permits continuous bypass without the need for circulatory arrest. Because the aorta is frequently anterior and the VSD is conoventricular, an infundibular incision in the right ventricle provides access to the VSD for baffling and then becomes the proximal site for connection of the right ventricle to pulmonary artery conduit. The ventriculotomy should be oblique, aiming toward the leftward and superior corner of the right ventricular infundibulum (Fig. 125-8). Care must be taken to avoid opening too close to the left coronary artery because this vessel usually arises from the left-facing sinus of the aorta. The advantage gained by placing the ventriculotomy as leftward as possible is that the right ventricle to pulmonary artery conduit can then be placed to the left of midline, avoiding compression by the sternum. The VSD and conal septum can be seen

FIGURE 125-8 ■ Rastelli procedure. Right ventriculotomy to expose the ventricular septal defect and aortic valve.

FIGURE 125-9 ■ Rastelli procedure. Baffle of left ventricular outflow through the ventricular septal defect to the rightward aorta.

easily through the ventriculotomy, and assessment is made regarding the need to enlarge the VSD. In conoventricular VSDs, conduction tissue runs on the inferior border of the VSD. Therefore, resection of the conal septum is safe, and the incision can be extended anteriorly to enlarge the VSD further if required. A tunnel-shaped synthetic patch (Dacron) is used to construct the baffle between the VSD and aortic annulus (Fig. 125-9). The pulmonary root can be closed through the ventriculotomy from the inside or from above once the pulmonary trunk is transected. The confluence of the pulmonary arteries should be mobilized to the left of the aorta as much as possible to facilitate connection with the right

ventricle to pulmonary artery conduit and avoid right pulmonary artery compression by the large aortic root. Once the distal anastomosis is created, the posterior portion of the conduit is sewn to the distal edge of the ventriculotomy. The anterior portion of the connection is created with homograft patch if the distal segment of the graft is available or the treated pericardium harvested at the beginning of the procedure can be used. Once the patient is off bypass, careful evaluation must be made of the adequacy of the left ventricular outflow by intraoperative echocardiography or by direct pressure measurement through needle puncture of the left ventricular cavity pressure and ascending aorta. A gradient higher than 10 to 15 mm Hg should be addressed surgically because this will likely progress over time. The most common place for residual obstruction is at the mid-portion of the VSD patch because this area requires the widest diameter of the semicircular patch. Placement of an additional patch can be done without removing the original baffle in cases in which the residual obstruction is at the level of the baffle.

Alternative techniques to avoid the use of conduits for right ventricle to pulmonary artery connection have been described by Lecompte and Vouhé in which the pulmonary arteries are mobilized and placed anterior to the aorta and a primary connection is made between the transected pulmonary trunk and the ventriculotomy. This connection is augmented with autologous pericardium, avoiding the use of a prosthetic conduit or homograft that will require replacement with growth.^{90,91}

Aortic Autograft Translocation and Arterial Switch. The potential long-term complications of the Rastelli operation are conduit obstruction, frequently caused by compression by the sternum because of the location of the conduit, or subaortic obstruction from a restrictive VSD or inadequate growth of the subaortic segment between the VSD and aortic annulus. To avoid these complications, an alternative procedure is to remove the aortic root from the infundibulum of the right ventricle, similar to a pulmonary autograft in normally related vessels (Fig. 125-10). Because this autograft is the

FIGURE 125-10 ■ Aortic root autograft. The aortic root is removed from the right ventricle in a manner similar to the method used for pulmonary root harvest for a pulmonary autograft procedure (*upper panel*). Enlargement of the left ventricular outflow tract and closure of ventricular septal defect (*lower panel*).

FIGURE 125-11 ■ Aortic root autograft. Right ventricle to pulmonary conduit, with the pulmonary arteries brought anterior to the aorta.

native aorta, the coronary arteries must be excised as circular buttons from the aortic root and mobilized away prior to resecting the aortic root. The left ventricular outflow can then be enlarged by incising across the conal septum into the existing VSD, or in cases in which there is no VSD or only a small restrictive defect, the incision is extended beyond the conal septum into the body of the left ventricle, similar to a Konno procedure.⁹² The aortic root autograft is then sewn to the native left ventricular outflow posteriorly, and a triangular-shaped synthetic patch is used to close the VSD up to the level of the aortic autograft. The coronary arteries are then reimplanted into the aortic root in their new location posteriorly, similar to an arterial switch procedure. A homograft conduit is then inserted between the right ventricular infundibulum and the central pulmonary arteries to establish right ventricle to pulmonary artery continuity. The pulmonary arteries can be mobilized and placed anterior to the aorta, as in the Lecompte operation, or in cases where the great vessel relationship is more side-by-side, the conduit can be placed to one side of the aorta (Fig. 125-11). The advantages of the aortic root translocation and arterial switch procedure are that the LVOT is by necessity enlarged to the size of the aortic root, the position of the aortic root with relation to the left ventricular outflow is more anatomic and therefore less tortuous, and the right ventricle to pulmonary artery conduit is in the anatomic position with respect to the right ventricle and therefore less susceptible to compression by the sternum.

Transposition of the Great Arteries with Double-Outlet Right Ventricle

Subpulmonary Ventricular Septal Defect. Double-outlet right ventricle with a subpulmonary VSD is an uncommon form of transposition that is frequently associated with unusual coronary artery anatomy or aortic

arch hypoplasia and coarctation. Subaortic stenosis from anterior deviation of the conal septum can also coexist with arch hypoplasia and at times requires a transannular patch to relieve the right ventricular outflow obstruction. When there is separation between the pulmonary valve and the mitral valve in double-outlet right ventricle and TGA, this combination is called the Taussig-Bing anomaly. In cases in which the VSD is conoventricular, two surgical options exist for anatomic repair. An intra-cardiac baffle technique has been described in which the left ventricular flow through the VSD is directed to the aorta that is usually rightward of the pulmonary valve, leaving room for right ventricular flow to go over the VSD patch to the pulmonary arteries.⁹³ The ability to baffle the VSD to the aorta without obstruction and while retaining the potential for growth is determined by the distance between the tricuspid valve annulus and the pulmonary root. In cases where the aorta is more posterior than the pulmonary valve, the pathway from VSD to aorta is more likely to be adequate. If this pathway is inadequate, there is a significant risk for late development of left ventricular outflow obstruction with growth of the child. The right ventricular outflow may also need to be enlarged with a patch in cases in which the left ventricle to aorta baffle occupies too much of the right ventricular outflow.

The more common method of achieving anatomic repair of TGA and double-outlet right ventricle is by a combination of closing the VSD to the pulmonary root, because it is closer, and then performing an arterial switch. This approach decreases the risk of late development of left ventricular outflow obstruction. However, because of the frequent association with single coronary artery and aortic arch hypoplasia, this operative approach is more technically demanding, and experience with complex coronary artery transfer is required. The surgical technique is similar to that of an arterial switch with mobilization of the pulmonary artery and branches, and

in cases with arch hypoplasia, dissection of the entire arch and branches is required. A single arterial cannula usually is sufficient except in severe arch obstruction or arch interruption in which a second arterial cannula through the arterial duct provides flow to the descending aorta. The VSD is best approached through an infundibular incision in the RVOT directly below the aortic root. A transatrial approach can be used, but because of the frequent extension of the VSD leftward and superior in the septum, adequate visualization of the most leftward extension of the VSD can be difficult with this approach. The frequent association of this form of TGA with a small or even hypoplastic tricuspid valve further complicates this approach. With the VSD closed, an arterial switch procedure is performed with similar techniques as described for simple transposition. In cases in which a coarctation or aortic arch hypoplasia is present, resection of the coarctation with patch augmentation of the aortic arch is required.

Noncommitted Ventricular Septal Defect. In rare cases, the VSD in double-outlet right ventricle is remote from the great vessels, either in the muscular septum or in the atrioventricular canal area. In these cases, enlargement of the VSD into the conoventricular area may be possible but likely requires extensive resection and may interfere with atrioventricular valve attachments or risk injury to conduction tissue. Although techniques have been described to achieve repair without VSD enlargement, the risk of late left ventricular outflow obstruction remains a significant concern.⁹⁴ For most of these children, management as single ventricle is likely to result in lower overall morbidity and mortality and is the preferred method in most centers.

Transposition of the Great Arteries with Aortic Arch Obstruction

TGA can be associated with coarctation of the aorta or aortic arch hypoplasia and can exist in the absence of a VSD although more commonly, a VSD is present along with other anomalies such as double-outlet right ventricle and "subaortic" obstruction.⁹⁵ An important aspect in the surgical management of neonates with the combination of TGA, VSD, and aortic arch hypoplasia is the recognition that other associated intracardiac anomalies, such as right ventricular outflow obstruction and right ventricular hypoplasia, often complicate repair.

The approach to repair of these lesions is similar to that for TGA with VSD with the additional need to mobilize the entire aortic arch and enough of the descending aorta to permit complete resection of ductal tissue and end-to-end anastomosis with or without patch augmentation. If the coarctation involves only the isthmus and junction with the arterial duct, then a simple resection with end-to-end anastomosis is sufficient. Frequently in infants with double-outlet right ventricle, the transverse arch is hypoplastic to varying degrees and requires patch augmentation.

Furthermore, there is almost always a significant size discrepancy between the ascending aorta and pulmonary trunk, with the latter being substantially larger. In these

cases, patch augmentation of the entire ascending aorta and arch, similar to the augmentation done for hypoplastic left heart syndrome, facilitates the arterial switch by eliminating the size discrepancy with the neo-aorta.

In cases in which the right ventricle is hypoplastic, careful evaluation of tricuspid valve annulus size and right ventricular volume should be done prior to surgery. In cases in which the tricuspid valve z-score is less than approximately 2.5 or the right ventricular volume is less than 15 mL/m², single ventricle management is probably a better option than an attempt at two-ventricle repair. If the right ventricle is borderline in size or there is concern that the combination of a mildly hypoplastic right ventricle and/or the infundibular incision will result in diminished right ventricular diastolic compliance, then leaving a small (≈ 3 to 4 mm) interatrial communication will permit right-to-left shunting, preserving systemic flow at the expense of mild cyanosis similar to repair of tetralogy of Fallot in infants.

Results

Transposition of the Great Arteries with Left Ventricular Outflow Tract Obstruction

Surgical repair of complex forms of transposition carries a significantly higher risk for morbidity and mortality than repair of simpler forms. Nevertheless, improvement in results with complex forms parallels those of simple transposition over the past 2 decades. In some respects, this improvement may be attributable to the recognition that the anatomic morphology of TGA with LVOT obstruction is heterogeneous, and the choice of operation becomes important. For example, the Rastelli operation, the aortic translocation, and arterial switch operation with resection of the obstructing LVOT tissue are three procedures that are designed to address the patient with TGA and LVOT obstruction. Thus, selection of the most appropriate operation that will meet the needs of the specific anatomy is important. Emani and colleagues reported their experience with 88 patients undergoing surgery for TGA with LVOT obstruction. Patients undergoing the Rastelli operation or aortic translocation were more likely to be older and to present with multilevel LVOT obstruction. Although all procedures can be performed with very low mortality, those undergoing the Rastelli operation were at highest risk for subsequent LVOT reintervention, whereas patients undergoing arterial switch operation with or without LVOT intervention or aortic translocation had a very low incidence of subsequent LVOT obstruction.⁹⁶ Long-term outcomes for the aortic translocation and primary arterial switch operation with LVOT resection are unavailable but will eventually be compared with results of the Rastelli experience. In a review of the 25-year experience with the Rastelli operation, Kreutzer and associates reported an overall mortality rate of 7% with no deaths in the most recent 7-year period.⁹⁷ On late follow-up, freedom from death or transplantation rates were 82%, 80%, 68%, and 52% at 5, 10, 15, and 20 years, respectively. Arrhythmias and sudden death accounted for almost one third of the late deaths and left ventricular dysfunction accounted for

another third. Freedom from death or reintervention rates were 53%, 24%, and 21% at 5, 10, and 15 years of follow-up, respectively. The most common indication for reintervention was conduit obstruction, but LVOT obstruction was also prevalent throughout the follow-up period.

Results with the Lecompte procedure (REV [réparation à l'étage ventriculaire] procedure) for TGA and LVOT obstruction are similar to those of the Rastelli procedure with respect to early mortality, with 3 of 42 patients dying early.⁹⁸ On late follow-up, however, there were no late deaths with a median follow-up of 5.4 years. Freedom from reoperation rates were $86\% \pm 8\%$ and $51\% \pm 22\%$ at 5 and 10 years, respectively, with the indication for reintervention being right ventricular outflow obstruction in all patients.

Transposition of the Great Arteries with Double-Outlet Right Ventricle

Transposition with double-outlet right ventricle, or the Taussig-Bing anomaly, still represents a significant surgical challenge with respect to early morbidity and mortality. In a 2001 review, Takeuchi and colleagues reported a 20% early mortality with side-by-side great vessel relationship and associated single coronary as a significant risk factor for death.⁹⁹ In the same report, infants that were managed as single ventricle with initial Glenn connection followed by Fontan had no operative deaths and no late deaths. Of the children undergoing an arterial switch, three required reoperation late—two for subaortic stenosis and one for supraaortic pulmonary stenosis. There were no late deaths in either group at an average follow-up of 24 months. Mavroudis and coworkers reported a series of 20 infants with Taussig-Bing anomaly comparing the arterial switch procedure with intracardiac tunneling technique described by Kawashima.¹⁰⁰ The operative mortality rate was 6% for the arterial switch group, and among the four children undergoing intracardiac baffle, there were no deaths. Of importance, however, was the fact that the average age at operation in these patients was 1.4 years, with most requiring at least one palliative procedure prior to repair. There was a high incidence of reoperation in the arterial switch group with aortic valve regurgitation a frequent complication late, likely reflecting the effects of pulmonary artery banding as a pre-switch palliation resulting in distortion of the neo-aortic root.

Transposition of the Great Arteries with Aortic Arch Obstruction

In recent reports, aortic arch hypoplasia or discrete coarctation have not been associated with increased mortality when the arterial switch and arch repair are undertaken together. Blume and associates reported a significant increase in overall mortality in children who had arch repair prior to arterial switch although the reasons for this were unclear.¹⁰¹ Tchervenkov and colleagues have reported no operative deaths in 12 patients undergoing arterial switch procedure for TGA with aortic arch obstruction and no late deaths after a mean follow-up

time of 42 months.⁹⁵ Other centers have reported a small but present incidence of aortic arch obstruction requiring reintervention with balloon dilation late.¹⁰²

Arterial Switch after Left Ventricular Retraining

There are two situations when left ventricular “retraining” might be necessary prior to arterial switch operation: (1) in patients with TGA and intact ventricular septum who present late, and (2) in patients that present with right ventricular dysfunction after atrial switch that is refractory to medical management. Surgical options to address the latter issue include tricuspid valve repair or replacement if there is significant tricuspid regurgitation, which has not had encouraging results, and heart transplantation, which is limited by donor availability and long-term complications. Perhaps the best option for these patients is conversion to an arterial switch. In this case, the left ventricle must be retrained to handle the systemic afterload in order for arterial switch to be successful. This is accomplished by “training” the left ventricle, imposing an afterload on the deconditioned left ventricle with the application of a pulmonary artery band. This can be performed via sternotomy without the use of CPB and is a long-term strategy, because one to three bandings over many months are typically required to adequately prepare the left ventricle.¹⁰³ The status of the left ventricle during banding must be closely assessed by echocardiography, magnetic resonance imaging, and cardiac catheterization, and various criteria have been developed to assess for adequate preparation of the ventricle. These include left ventricular mass index and left ventricle/right ventricle pressure ratio.

These procedures are significant undertakings, with substantial intensive care unit and hospital stays but when accomplished successfully can offer good long-term outcomes. Poirier and Mee reported a series of 84 patients who underwent arterial from atrial switch conversion with an 85% overall survival. Normal late left ventricular function and right ventricular function were seen in approximately 90% of these patients. The best results were obtained in patients undergoing conversion prior to adolescence, with less predictable results and higher mortality rates observed in older patients.¹⁰³

In unoperated infants who present after the early neonatal period, preliminary pulmonary artery banding followed closely by arterial switch operation (rapid two-stage switch) banding has been performed. However, the data from more recent experiences suggest that this approach is seldom required; pulmonary artery banding for left ventricular retraining following atrial switch often takes much longer, averaging 19 months in some reports.

SUMMARY

The treatment of TGA has evolved rapidly. Current results with the arterial switch operation are excellent and make this procedure the standard of care for neonates with this diagnosis. Experience is being gained with complex forms of transposition, allowing safe anatomic

repair for these patients as well. Continued surveillance of patients following repair is necessary to detect and deal with potential long-term complications in these patients.

Anatomic Repair

SUMMARY

Congenitally corrected transposition of the great arteries (ccTGA) is a rare defect, seen in approximately 0.5% of patients with congenital heart defects.^{1,2} It entails discordance of the atrioventricular (AV) connections and discordance of the ventricular arterial connections, so there is double discordance. The morphology of the heart is distinctly abnormal, but the circulatory system is physiologically normal. Commonly, ccTGA is associated with ventricular septal defects (VSDs), pulmonary stenosis, dysplasia of the tricuspid valve, and conduction abnormalities (e.g., heart block usually develops).³⁻⁵ Although this condition can be compatible with a normal life span,^{6,7} the majority of patients require surgery to repair the associated cardiac anomalies, and many develop heart failure

because of systemic morphologic right ventricular (mRV) dysfunction, usually with tricuspid valve regurgitation.⁸⁻¹¹ Historically, surgery was directed toward managing the associated cardiac anomalies, closing the VSD, relieving pulmonary stenosis, repairing or replacing the tricuspid valve, and placing pacemakers to manage the conduction abnormalities. This so-called classical or conventional (physiologic) repair maintains the mRV as the systemic ventricle. More recently, the morphologic left ventricle (mLV) has been restored to the systemic circulation by an atrial switch (Senning or Mustard procedure) and an arterial switch or Rastelli procedure to connect the aorta to the mLV.¹²⁻¹⁵ This is referred to as *anatomic repair*, and it is the preferred technique for symptomatic patients.

GENERAL DESCRIPTION AND MORPHOLOGY

In the usual *situs solitus* arrangement with normal systemic and pulmonary venous drainage, the ventricular apex of the heart usually points to the left side of the patient, but *mesocardia* and *dextrocardia* are common, occurring in up to 20% of cases.^{4,16} Malposition of the ventricular mass so that it comes to lie in front of the atria and venous drainage to the heart can make surgical access to these structures difficult. In *situs inversus*, which occurs in approximately 5% of cases, *mesocardia* and *levocardia* can occur. It seems that extreme malposition of the ventricular mass is commonly associated with severe pulmonary stenosis or pulmonary atresia in association with a large VSD.¹⁶ Characteristically, the aorta is anterior and to the left side of the more deeply placed pulmonary artery—hence the older term for this condition, *L-transposition*. However, the aorta can be more anterior to the pulmonary artery and even on the right side. Likewise, the mLV is usually to the right and slightly inferior to the mRV; however, the position of the ventricles relative to each other can show great variability.³ The ascending aorta is often short and well over to the left side of the mediastinum in *situs solitus*, again making surgical access difficult. In the rarer form of *situs inversus*, the aorta lies anterior and to the right of the posterior pulmonary artery and is usually more accessible.

In ccTGA without associated cardiac anomalies (sometimes referred to as *isolated ccTGA*), the circulation is physiologically normal, with systemic venous return passing through the right atrium, through the mitral valve, and then into the mLV. Here, the mLV pumps blood through the pulmonary arteries into the lungs, from whence it returns to the pulmonary veins and to the left atrium. The blood flow continues through the tricuspid valve and into the mRV, where it is pumped around the systemic circulation via the aorta (Fig. 126-1). Without other cardiac anomalies, patients with congenitally corrected transposition can survive well into adult life without symptoms. It is the associated anomalies—VSD, pulmonary stenosis, abnormalities of the tricuspid valve, and development of arrhythmias or complete heart block—that predispose the patient to the development of cardiac failure early in life. However, even patients with isolated ccTGA can develop systemic ventricular (i.e., the mRV) dysfunction leading to congestive cardiac failure in childhood or early adult life, but predicting which patients will do so is one of the many challenges in managing the condition.

Ventricular Septal Defect

Ventricular septal defect occurs in approximately 70% of cases.⁴ It is usually isolated and in the perimembranous region. Isolated VSDs can also occur in the infundibular region, and they may be multiple. When associated with severe pulmonary stenosis or pulmonary atresia, the VSD is usually subaortic and large, extending from the perimembranous region to beneath the aortic valve. This is important, because it allows the VSD to be tunneled to

FIGURE 126-1 ■ Diagram of congenitally corrected transposition of the great arteries. Ao, Aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; MV, mitral valve; PA, pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava; TV, tricuspid valve.

the aorta when the mLV is committed to the aorta as a systemic ventricle.

Pulmonary Outflow Tract Obstruction (Morphologic Left Ventricular Outflow Tract Obstruction)

Obstruction to the pulmonary artery from the LV is common in congenitally corrected transposition, occurring in probably up to 50% of cases.^{4,17} This is partly because the pulmonary artery is between the mitral and tricuspid valves, deep toward the crux of the heart. A potential exists for hypoplasia of the subpulmonary outflow tract. When hypoplasia occurs in association with a VSD, there may be accessory tissue around the VSD, which can balloon into the pulmonary valve. Accessory tissue tags can prolapse into the outflow tract from the mitral or the tricuspid valves, and over time fibrous tissue can be deposited in the subpulmonary area of the mLV outflow tract. Accessory attachments of the mitral or tricuspid mitral valve through the VSD can cause obstruction beneath the pulmonary valve. In the majority of these cases, the pulmonary valve and annulus are stenotic, and the morphology falls into the spectrum of requiring a Rastelli-type procedure to commit the mLV to the aorta. However, each case needs careful assessment because those with a normal-sized pulmonary valve and accessory tissue in the outflow tract may be more suitable for arterial switch and resection of tissue in the LVOT.

Mitral and Tricuspid Valves

The mitral valve is usually normal in congenitally corrected transposition. There are usually two well-formed papillary muscles on the lateral wall of the LV.

Occasionally, we have noted a cleft in the septal component of the mitral valve.¹⁸

The tricuspid valve, however, is a markedly different proposition. The valve itself may be intrinsically normal, but through dilation of the ventricle and the tricuspid valve annulus, it can become progressively regurgitant over time. However, more commonly the valve is dysplastic, and this predisposes to valvular regurgitation. There is a marked association with dysplasia and displacement of the septal components of the tricuspid valve well down into the body of the RV, sometimes for several centimeters, and this, in the setting of systemic pressures in the RV, can create severe tricuspid valve regurgitation. We have noted double orifices in the tricuspid valve, abnormal septal clefts, and marked annular dilation. Because of difficult access and the great variability in the pathology in this valve, repair can be difficult.¹⁸⁻²⁰

The Ebsteinoid displacement of the tricuspid valve into the body of the mRV is not associated with any atrialization of the RV free wall. Neither do these valves demonstrate any of the failed delamination or multiple leaflet fenestrations typical of Ebstein's anomaly. Thus, it is not strictly equivalent to an Ebstein tricuspid valve in a normal heart, and the term simply reflects the apical displacement of the tricuspid valve in this setting. In addition, when functioning at lower pulmonary pressures after a double-switch procedure, the regurgitation is markedly reduced; that is, it is not a low-pressure regurgitant valve, but tends to be a high-pressure regurgitant valve. The improved performance of the tricuspid valve after double-switch is also related to the more favorable septal alignment, which improves coaptation of the septal leaflet in the lower-pressure RV.

Rarely, straddling and override of the AV valves can occur, usually in association with a degree of hypoplasia of the LV or RV, many merging into the spectrum of double-inlet LV.²¹⁻²³ These hearts are managed according to the principles of any functionally univentricular circulation.

Other Associated Cardiac Anomalies

Abnormalities of the aortic arch, including interruption of the aorta and coarctation, can occur. We have seen a 20% incidence of coarctation or arch hypoplasia and 2% incidence of interruption. As might be expected, none were associated with pulmonary stenosis or atresia.²⁴

Coronary Arteries

Usually, the anterior sinus of the aortic valve gives rise to what would normally be the right coronary artery (Fig. 126-2). This divides to pass down the line of the interventricular septum as the anterior descending coronary artery. The other circumflex branch passes in the AV groove between the right atrium and the LV. The posterior sinus of the aortic valve gives rise to the morphologically right coronary artery passing in the AV groove between the left atrium and the RV. Almost universally, the coronary artery ostia face the corresponding sinuses of the pulmonary valve. This is an important consideration in the arterial switch procedure.

FIGURE 126-2 ■ Disposition of coronary arteries in congenitally corrected transposition of the great arteries. Ao, Aorta; Cx, circumflex coronary artery; LAD, left anterior descending coronary artery; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RCA, right coronary artery; RV, right ventricle.

Conduction System

The abnormalities of the conduction system in congenitally corrected transposition have been well described.²⁵⁻²⁸ Because of malalignment of the AV septum, there is an anterior and a superior AV node in the atrial septum adjacent to the mitral and pulmonary valve. These nodes give rise to a penetrating bundle that passes around the free wall of the LV in a subendocardial position anterior to the pulmonary valve. The bundle then sweeps down onto the ventricular septum in the mLV, supplying a left bundle branch over the septal surface of the LV and a penetrating right branch into the mRV. The sinus node is in a normal position adjacent to the entrance of the superior vena cava into the right atrium (Fig. 126-3).

In the rarer form of situs inversus, the normally positioned AV node of that is in the triangle of Koch superior to the coronary sinus persists and gives a penetrating branch to the ventricular septum but inferior and posterior to the pulmonary valve. These pathways are important because in situs solitus, when there is a VSD in the perimembranous region, the bundle passes superior to the VSD around the pulmonary outflow tract and then down on the leftward or anterior margin of the VSD. In the rarer forms of situs inversus, the bundle passes on the inferior margin of the VSD on the mLV surface. Occasionally, both posterior and anterior AV nodes exist, and a loop of conduction tissue can encircle the VSD when it is present. Sutures to close the VSD are ideally placed from the mRV surface of the VSD to avoid damaging the conduction system.²⁹ The longer course of the conduction system to the ventricles associated with the malalignment of the atrioventricular septum has been given as a reason for the development of complete heart block.

FIGURE 126-3 ■ Disposition of conduction system in congenitally corrected transposition of the great arteries and relationship to ventricular septal defect (VSD). Ao, Aorta; AV node, atrioventricular node; IVC, inferior vena cava; LV, left ventricle; MV, mitral valve; PA, pulmonary artery; RA, right atrium; RV, right ventricle; SA node, sinus atrial node; SVC, superior vena cava.

CLINICAL PRESENTATION OF CONGENITALLY CORRECTED TRANSPOSITION OF THE GREAT ARTERIES

A patient's clinical presentation depends on the presence or absence of associated cardiac anomalies. Without such anomalies, patients may be entirely free of symptoms well into late adult life; however, this is an unusual, if not rare, situation. More commonly, even in the absence of associated malformations, a degree of congestive cardiac failure develops over the lifetime of the patient, usually aggravated by the development of progressive tricuspid regurgitation.⁷

When associated with a VSD, presentation in early infancy is usually with congestive cardiac failure resulting from pulmonary overflow from the left-to-right shunt. In view of heart failure and the risks for pulmonary hypertension and progression to pulmonary vascular disease, medical management with diuretics and angiotensin-converting enzyme inhibitors is usually supplemented with pulmonary artery banding. VSD in this condition usually occurs with a degree of congenital pulmonary stenosis and can produce a nicely balanced circulation without heart failure or marked cyanosis. The patient may be well and in stable condition for many years without the need for medical or surgical intervention. When the pulmonary stenosis progresses or if it is severe initially, cyanosis may be the cause of clinical presentation, and early systemic-to-pulmonary shunting may be required. Pulmonary atresia with a large perimembranous VSD extending to the subaortic region is a well-recognized combination of associated cardiac anomalies,

and a neonate in this situation usually exhibits severe cyanosis and requires an early systemic shunt.

A small percentage of patients are seen in early infancy with severe congestive cardiac failure, sometimes associated with pulmonary hypertension. This is usually associated with marked tricuspid regurgitation secondary to dysplasia of the tricuspid valve, and it is often associated with a VSD that could aggravate the heart failure. Early surgical management is mandatory in these critically ill infants.¹⁸

Thus, there is a wide range of possible presentations that vary with the intracardiac anatomy, ranging from asymptomatic adults to infants in severe congestive cardiac failure. Depending on the degree of pulmonary stenosis or atresia, some patients may have well-balanced circulation with mild cyanosis, whereas others have severe cyanosis requiring systemic shunts in the neonatal period. Throughout the patient's life, the clinical course can be complicated by the development of complete heart block and other cardiac arrhythmias.

PROBLEM OF THE TRICUSPID VALVE AND THE MORPHOLOGIC RIGHT VENTRICLE IN THE SYSTEMIC CIRCULATION

The main concern highlighted in many papers^{8-11,19,30-32} has been the unpredictable way the mRV in association with tricuspid valve regurgitation can fail when it remains as the systemic ventricle. The development of RV failure can occur primarily without previous surgical intervention, and it is usually associated with dysplasia of the tricuspid valve, causing tricuspid regurgitation. RV failure can also occur secondarily after conventional repair of associated cardiac defects such as VSD closure or the relief of pulmonary stenosis or atresia when the RV remains in the systemic circulation.

The deterioration in the RV function associated with tricuspid regurgitation can also develop insidiously over many years without associated cardiac anomalies. There is then gradual deterioration of RV function with worsening of tricuspid regurgitation in association with the volume loading of the RV. These changes can commence in childhood or infancy and progress at a variable rate.^{19,30} When these changes are associated with dysplasia or Ebsteinoid displacement of the tricuspid valve, deterioration can be rapid. Secondary deterioration of ventricular function and development of tricuspid regurgitation are recognized to occur in an unpredictable way after conventional repair of associated cardiac anomalies. Thus, VSD closure with pulmonary artery debanding may be successful with the RV in the systemic circulation, although over time RV failure with tricuspid regurgitation can follow such a repair. In the situation of pulmonary atresia with VSD, closure of the VSD and placement of a valved conduit from the mLV to the pulmonary arteries may later be associated with the development of tricuspid regurgitation and RV failure.

It therefore seems that, either primarily or secondarily after conventional repair, the RV in the systemic

circulation is prone to failure and severe tricuspid regurgitation. Once the tricuspid regurgitation has developed, the volume loading of the RV accentuated by any systemic shunts or VSD can cause further dilation of the tricuspid valve and its annulus, creating more regurgitation, so that a vicious cycle of heart failure with increasing tricuspid regurgitation follows. The difficulty is recognizing which patients are likely to develop these complications after a conventional repair and then determining the best surgical procedure to repair their heart.

The development of mRV systemic failure without previous surgical intervention is almost always associated with dysplasia of the tricuspid valve. The suggested mechanism is that dilation of the RV, in association with its volume loading resulting from tricuspid regurgitation, displaces the ventricular septum into the mLV. The displacement of the septal components of the tricuspid valve prevents coaptation of leaflet tissue, thus accentuating the regurgitation. This vicious cycle of tricuspid valve dilation and ventricular volume overload with increasing regurgitation continues.¹⁹ In secondary mRV failure following conventional closure of VSD or relief of pulmonary valve stenosis, the fall in the mLV pressure and realignment of the ventricular septum to the pulmonary ventricle can have the same effect by creating tricuspid regurgitation. That can then be aggravated by volume overloading of the mRV. This is thought to be the mechanism of the development of tricuspid regurgitation and RV failure, which is supported by the observation that, in placing the pulmonary artery band to train the mLV, the tricuspid regurgitation can be acutely reduced by realignment of the ventricular septum.^{18,19} If this is the mechanism of mRV failure, then tricuspid regurgitation and RV failure can be expected to occur after conventional repair.

Anatomic repair of ccTGA restores the mLV to the systemic circulation by redirecting the systemic and pulmonary venous returns—via a Senning or Mustard procedure—and then performing an arterial switch if the pulmonary valve and LV outflow tract were unobstructed, or a Rastelli-type procedure with rerouting of the VSD to the aorta when the VSD was suitably placed beneath the aortic valve.²⁹ Several groups reported successful double-switch and Rastelli atrial switch procedures, showing that the mLV could be restored to the systemic circulation.^{12-15,33} The underlying theme in these reports was that the mLV restored to the systemic circulation could be a better long-term systemic ventricle and would have the added benefit of preventing the development of RV failure. In the double-switch procedure, besides restoring the mLV and mitral valve to the systemic circulation, the mRV becomes the pulmonary ventricle, works at lower pressures, and is decompressed. The amount of tricuspid regurgitation can be immediately reduced because of the lower working pressures of the RV with minimal need for any repair or replacement of the tricuspid valve. Maintenance of the alignment of the ventricular septum or its displacement into the RV cavity would aid in maintaining competency of the tricuspid valve by preventing displacement of the septal leaflet of the tricuspid valve. In essence, the mRV is now working as a pulmonary ventricle at low pulmonary artery pressures and can function satisfactorily in that setting.

Although accentuating the interrelationship between tricuspid valve regurgitation, RV volume overloading, and RV failure, several papers have highlighted the possible problem of RV myocardial ischemia as a cause of RV failure. The RV, working at systemic pressures with resultant hypertrophy of the myocardium, may not have sufficient coronary vascular supply. This results in ischemia of the RV myocardium, which, together with volume loading secondary to tricuspid valve regurgitation, may be the determining factor in RV failure in this condition.³⁴⁻³⁶
